Abstract

Experiments involving boron incorporation into brucite (Mg(OH)$_2$) from magnesium-free artificial seawater with pH values ranging from 9.5 to 13.0 were carried out to better understand the incorporation behavior of boron into brucite. The results show that both concentration of boron in deposited brucite ([B]$_d$) and its boron partition coefficient ($K_d$) between deposited brucite and final seawater are controlled by pH of the solution. The incorporation capacity of boron into brucite is much stronger than that into oxides and clay minerals. The isotopic compositions of boron in deposited brucite ($\delta^{11}$B$_d$) are higher than those in the associated artificial seawater ($\delta^{11}$B$_{isw}$) with fractionation factors ranging between 1.0177 and 1.0569, resulting from the preferential incorporation of B(OH)$_3$ into brucite. Both boron adsorptions onto brucite and precipitation reaction of H$_3$BO$_3$ with brucite exist during deposition of brucite from artificial seawater. The simultaneous occurrence of both processes determines the boron concentration and isotopic fractionation of brucite. The isotopic fractionation behaviors and mechanisms of boron incorporated into brucite are different from those into carbonates. Furthermore, the isotopic compositions of boron in modern corals might be affected by the existence of brucite in madrepore and the preferential incorporation of B(OH)$_3$ into brucite. An exploratory study for the influence of brucite on the boron isotopic composition in modern corals is justifiable.

1 Introduction

Mg is a common trace element in the *scleractinian* corals and Mg/Ca ratio has been used to investigate paleothermometry of seawater (Watanabe et al., 2001; Marshall and McCulloch, 2002; Mitsuguchi et al., 2008; Allison et al., 2010). Mg can exist in the form of brucite in corals (Smith and Delong, 1978; Nothdurft et al., 2005) and Mg content in *scleractinian* corals varies between different genera and localities (Fallon et al., 1999). Nothdurft et al. (2005) studied brucite in living *scleractinian* corals colonies
Acropora, Pocillopora, Porites) from subtidal and intertidal settings in the Great Barrier Reef, Australia, and subtidal Montastrea from the Florida Keys, United States. Their results suggested that high containing activity combined with high pH and low $\rho$CO$_2$ led to localized brucite precipitation in organic biofilms of coral skeletons and that brucite in living coral skeletons is an indicator of extreme microenvironments in shallow-marine settings. The occurrence of brucite in corals could be responsible for reported anomalies in Mg/Ca vs. sea-surface temperature (SST) plots in corals (Nothdurft et al., 2005). However, little attention has been paid to the influence of brucite on the boron isotopic composition of corals.

Studies of boron isotopic compositions of minerals have been developed (Palmer and Swihart, 1996; Pokrovsky and Schott, 2004; Pokrovsky et al., 2005; Sanchez-Valle et al., 2005). In minerals as clay and other layered hydroxides, surface charge properties play an important role by changing the apparent acid-base equilibrium constant (Sanchez-Valle et al., 2005). Boric acid can inhibit the dissolution of brucite (Pokrovsky et al., 2005) and the tendency of adsorbing boron onto brucite or hydrous ferric oxide (HFO) is relatively strong (Petric et al., 1998; Wang, 2003; Liu et al., 2004). Peak et al. (2003) investigated the mechanism of boric acid ($\text{B(OH)}_3$) and borate ($\text{B(OH)}_4^-$) adsorption onto HFO, suggesting that $\text{B(OH)}_3$ may be the main species adsorbed onto HFO. Liu et al. (2004) studied the mechanism of boron absorption by brucite, suggesting that the adsorption was controlled by solution pH and only the $\text{B(OH)}_4^-$ species was absorbed onto the brucite surface. However, the influence of brucite on boron isotopic fractionation during adsorption is not researched, so that the mechanism of boron incorporated into brucite is unclear.

In recent years, topics such as the reconstruction of ancient seawater pH using the isotopic composition of boron in bio-carbonates, the calculation of the past $\rho$CO$_2$, and the influence of these two factors on changes in the ancient climate, have become important issues for the international boron isotope geochemistry community (Vengosh et al., 1991; Hemming and Hanson, 1992, 1995; Spivack et al., 1993; Gaillardet and Allègre, 1995; Sanyal et al., 1995, 1997; Palmer et al., 1998; Pearson and Palmer,
Whether the $\delta^{11}\text{B}$ of bio-carbonate is equal to that of $\text{B(OH)}_4^-$, and what the theoretic fractionation factor ($\alpha_{4-3}$) between $\text{B(OH)}_4^-$ and $\text{B(OH)}_3$ is, have emerged as the main questions involved in these issues. A series of inorganic calcite precipitation experiments have shown that $\text{B(OH)}_4^-$ is the dominant species incorporated into calcite (Palmer et al., 1987; Hemming et al., 1995; Sanyal et al., 1996, 2000). However, Klochko et al. (2009) recently found that both trigonal and tetrahedral coordinated boron existed in biogenic and hydrothermal carbonates. Inorganic calcite precipitation experiment has been carried out by Xiao et al. (2006), indicating that the $\delta^{11}\text{B}$ of inorganic calcium carbonate did not in parallel with the calculated curve of $\text{B(OH)}_4^-$, but deviated increasingly from the parallel trend as pH increased. When pH was increased to a certain value, the isotopic fractionation factor of boron between precipitation and solution was greater than 1. Xiao et al. (2006) reasoned that the presence of $\text{Mg}^{2+}$ or other microelements was the main reasons of this observation and concluded that $\text{B(OH)}_3$ may incorporate preferentially into brucite. If this is true, the isotopic compositions of boron in modern corals might be affected by the existence of brucite in madrepore and the preferential incorporation of $\text{B(OH)}_3$ into brucite.

In this study, experiments on the incorporation of boron during the deposition of brucite from magnesium-free artificial seawater at various pH values were carried out. The incorporation species of boron into brucite and the boron isotope fractionation during deposition of brucite were discussed. This result will shed some light on the application of boron isotope-paleo-pH proxy in corals.

2 Methods

2.1 Reagents and equipment

1.0 M HCl, 0.5 M NaOH, and 0.5 M MgCl$_2$ were prepared using boron-free water with twice distilled HCl (GR), NaOH (GR), and MgCl$_2$ (GR), respectively. The concentration
of the Cs$_2$CO$_3$ (99.994% purity) solution used in our study was 12.3 g Cs L$^{-1}$. A suspended graphite solution was prepared using SP graphite confected with 80% ethanol and 20% water. For a mannitol concentration of 1.82 g L$^{-1}$, GR mannitol confected with boron-free water was used. The boron-free water was obtained by using 18.2 MΩ milliQ of water exchanged with an Amberlite IRA 743 boron specific resin. A GV IsoProbe T-single magnetic sector thermal ionization mass spectrometer was used, as were a 2100 type and UV-2100 type spectrophotometer from Shanghai Unico Ltd. Throughout the entire experiments, vessels of Teflon, polyethylene or chert were used for avoiding boron contamination.

2.2 Magnesium-free artificial seawater

Magnesium-free artificial seawater was prepared according to the Mocledon’s method (see http://zhidao.baidu.com/question/26278104.html?fr=qrl). The chemical composition of the magnesium-free artificial seawater is given in Table 1. In order to get sufficient quantities of boron for precise isotopic analysis in the precipitated Mg(OH)$_2$, boron concentration in the artificial seawater was adjusted to 45.9 ppm, approximately 10 times that of normal seawater (~4.5 ppm). According to the result reported by Ingri et al. (1957), there was no polyborate species present when the boron concentration of aqueous solution was 45.9 ppm. The pH value and boron isotopic composition of the initial artificial seawater was 3.64 and $-7.00 \pm 0.07\permil$, respectively. Since magnesium-free artificial seawater was used in our experiments, no brucite was deposited while the pH was being adjusted. Brucite was deposited only when MgCl$_2$ was added after the pH adjustments were completed.

2.3 Experimental deposition of brucite

Deposition experiments were carried out in a pH-controlled system at a temperature of $22 \pm 0.5$°C in a super-clean laboratory (100 Class). Firstly, about 200 mL of artificial seawater was placed inside a plastic beaker. Solutions of NaOH were slowly added to
each beaker to achieve the following range of pH values: 9.50, 10.00, 10.50, 11.00, 11.50, 12.00, 12.50, and 13.00. 8 mL of MgCl$_2$ solution was then added dropwise into the artificial seawater with different pH values. During this process, NaOH was added to keep the pH at the predetermined pH values as the brucite was deposited. The pH fluctuations were measured by a pH meter with a precision of 0.01. A magnetic stirrer was used during the experiments process to ensure the reactions were completed. The experiment was terminated after 8 mL of MgCl$_2$ was added. After mixing well the deposit and solution, the mixture was divided into two parts evenly. One was encountered filtration by pumping immediately to isolate deposit from solution (defined as a repose time $T_r = 0$ h) and the other was encountered filtration by pumping after repositing for 20 h (defined as a repose time $T_r = 20$ h). The separated solution was placed in air-tight plastic bottles, and the brucite deposit was washed with boron-free water until Cl$^-$ was no longer detected. Then the deposited material was dried at 60°C and placed in air-tight plastic bottles.

2.4 Separation of boron from the samples

In preparation for isotopic measurement, boron was extracted from the artificial seawater and the brucite using a two-step chromatographic technique (Wang et al., 2002). About 0.5 mL of Amberlite IRA 743 boron-specific resin with 80–100 mesh was placed in a polyethylene column with a diameter of 0.2 cm. The length of the resin bed was 1.5 cm. About 200 mg of brucite was first dissolved using a slightly excessive amount of boron-free HCl solution, passed through a column filled with Amberlite IRA 743 resin, and then eluted using approximately 5 mL of 0.1 M HCl at 75°C. An amount of mannitol approximately equimolar to the boron content was added to the eluate, which was then desiccated to near dryness by partial evaporation in a super clean oven with laminar flow at 60°C (Xiao et al., 2003). The solution was then loaded again into the column filled with a mixed resin composed of 0.5 mL cation-exchange resin (H$^+$ form) and 0.5 mL anion-exchange resin (ion-exchange II, HCO$_3^-$ form). The boron was eluted by 5 mL of boron-free water. The eluate was evaporated again at 60°C to produce a
solution with a boron concentration of about 1 µg B/µL for isotopic measurement. The procedures for extracting boron in the liquid samples were the same as those described above. The total boron blank in chemical process and filament loading was determined by isotope dilution mass spectrometry (IDMS) to contain 46 ng of boron.

2.5 Measurements of boron concentration and isotopic composition

The boron concentrations were determined by the azomethine-H spectrophotometric method. One mL of sample solution, 2 mL of buffer solution, and 2 mL of azomethine-H solution were added in that order. After thorough mixing, each solution was allowed to stand for 120 min. The absorption of the boron-azomethine-H complex was measured at 420 nm using a spectrophotometer. The external precision of the azomethine-H method used here was 2%.

The isotopic compositions of boron in all samples were measured by a GV IsoProbe T single magnetic sector thermal ionization mass spectrometer and the P-TIMS method using Cs$_2$BO$_2^+$ ions with a graphite loading (Xiao et al., 1988). Two µL of graphite slurry was first loaded onto a degassed tantalum filament, and then approximately 1 µL of sample solution containing about 1–4 µg of boron and an equimolar amount of mannitol were also loaded. This was followed by 1–2 µL of a Cs$_2$CO$_3$ solution containing an equimolar amount of cesium. The loaded material was dried by heating the filament at 1.2 A for 5 min.

The data were collected by switching the magnetic field between the masses 308 ($^{133}$Cs$_2^1$B$^{16}$O$_2^+$) and 309 ($^{133}$Cs$_2^2$B$^{16}$O$_2^+$), and the intensity ratios of the ion beams at masses 308 and 309 ($R_{309/308}$) were calculated. Calibrated with oxygen isotopes, the $^{11}$B/$^{10}$B ratio was calculated as $R_{309/308}$. The isotopic composition of boron was expressed as an $\delta^{11}$B value according to the following formula:

$$\delta^{11}\text{B}(‰) = \left[\left(\frac{^{11}\text{B}}{^{10}\text{B}}\right)_{\text{sample}} / \left(\frac{^{11}\text{B}}{^{10}\text{B}}\right)_{\text{standard}} - 1\right] \times 1000$$
Here the standard material is NIST SRM 951, the recommended value of which is 4.04362 ± 0.00137 (Catanzaro et al., 1970). The measured average $^{11}\text{B}/^{10}\text{B}$ ratio of NIST SRM 951 was 4.0525 ± 0.0027 ($2\sigma_m$, $n = 5$).

3 Results and discussion

3.1 Dissolved boron species and boron isotope in seawater

The dominant aqueous species of boron in seawater are $\text{B(OH)}_3$ and $\text{B(OH)}^-_4$. The relative proportions of these species are a function of pH (Fig. 1a) and given by the following relation:

$$\text{B(OH)}_3 + \text{H}_2\text{O} \rightarrow \text{B(OH)}^-_4 + \text{H}^+ \quad (1)$$

Figure 1 shows the theoretical distribution of boron species as a function of pH for seawater. At low pH ($\text{pH} < 7$), virtually all of the boron in seawater is in the $\text{B(OH)}_3$ species; conversely, at high pH ($\text{pH} > 10$), virtually all of the boron is in the $\text{B(OH)}^-_4$ species (Fig. 1a). The isotope exchange reaction between these species is given by:

$$^{10}\text{B(OH)}_3 + ^{11}\text{B(OH)}^-_4 \rightarrow ^{11}\text{B(OH)}_3 + ^{10}\text{B(OH)}^-_4 \quad (2)$$

The distribution of species and the isotope exchange reaction are solved simultaneously to give the isotopic composition of the individual boron species vs. pH for seawater (Fig. 1b). The abundances of two stable isotopes $^{11}$B and $^{10}$B at pH 8 make up approximately 80% and 20% of the total boron, respectively. Modern seawater has a boron concentration of about 4.5 ppm, and a consistent, worldwide $\delta^{11}$B isotopic composition of +39.5‰ relative to NIST SRM 975. Only the $\text{B(OH)}^-_4$ incorporated into the marine bio-carbonates is one of the essential hypotheses for using boron isotopic composition in marine bio-carbonate to reconstruct the paleo-environment.
3.2 The partition coefficient of boron between Brucite and final seawater

The boron concentrations and the partition coefficients ($K_d$) between brucite and final seawater are listed in Table 2, and shown in Fig. 2. The results are showed as follows:

1. The variation trend of the results for $T_r = 0\,\text{h}$ and $T_r = 20\,\text{h}$ are basically the same (Fig. 2a), indicating the incorporation of boron into brucite deposit is instantaneous, and the reaction time is not a main limiting factor. This finding is consistent with the previous study (Liu et al., 2004).

2. When pH is lower than 10, $[B]_{fsw}$ decreases as the pH increases, and reaches the lowest value at pH 10 (Fig. 2a). This indicates that the amount of boron incorporated into deposited brucite increases as pH increases, and reaches the highest value at pH 10. $[B]_{fsw}$ increases quickly at higher pH values, and no smooth trend is observed, indicating that the amount of incorporated boron decreases quickly.

3. When pH is lower than 10, $K_d$ increases as the pH increases (Fig. 2b). The $K_d$ reaches its highest values of 487.5 and 494.2 for $T_r = 0\,\text{h}$ and $T_r = 20\,\text{h}$ at pH 10, respectively. When pH is higher than 10, $K_d$ decreases and shows a mild trend after pH 12.

The $K_d$ between brucite deposit and final seawater can be shown as:

$$K_d = (f \times K_{d3} + K_{d4})/(1 + f).$$

$$K_d = ([B_3]_{\text{solid}} + [B_4]_{\text{solid}})/([B_3]_{\text{fluid}} + [B_4]_{\text{fluid}}),$$

$$K_{d3} = [B_3]_{\text{solid}}/[B_3]_{\text{fluid}},$$

$$K_{d4} = [B_4]_{\text{solid}}/[B_4]_{\text{fluid}},$$

$f$ is the ratio of $B(OH)_3$ to $B(OH)_4^-$ in solution. This equation indicates that $K_d$ is not only related with $K_{d3}$ and $K_{d4}$, but also with the fraction of $B(OH)_3$ in solution. The $K_d$ between clay minerals and seawater is 3.60 at $T = 5\,^\circ\text{C}$ and pH 8.45 (Palmer, 1987), but the highest $K_d$ in our experiments is 494 at pH 10, which is much higher than 3.6. It indicates that the $K_{d3}$ is much greater than...
Boron isotope fractionation during brucite deposition

Introduction

Conclusions

References

Tables

Figures

K_{d4}, i.e. the incorporation capacity of B(OH)$_3$ into brucite is much higher than that of B(OH)$_4^-$ and the $K_{d3}$ contribution is dominating. The quantity of brucite reaches its highest at pH 10, indicating the reaction equivalence point of brucite deposition occurs approximately at pH 10. The $K_d$ also reach its highest at pH 10. When pH is higher than 10, the $f$ and $K_{d3}$ decreases while $K_{d4}$ increases as the increasing pH. Although the increasing concentration of OH$^-$ in solution can influence the adsorption of B(OH)$_4^-$ (Keren et al., 1981), the adsorption of B(OH)$_4^-$ continues, and the $K_{d4}$ still increases perhaps. Because of $K_{d3}$ is greater than $K_{d4}$, the decreasing of $K_{d3}$ is dominating, so that the $K_d$ decreases with the increasing pH. In the studies of Xu and Ye (1997), the point of zero charge (PZC) of brucite is close to 11.9, which is approximates to the inflexion point (pH 12) in our experiment. When pH is higher than PZC, anions will not be adsorbed by goethite and gibbsite (Kingston et al., 1972), so that the adsorption ability of B(OH)$_4^-$ by brucite decreases greatly when pH is higher than the PZC of brucite. Therefore, $K_d$ should monotonically decrease with increasing pH as well.

Boron removal experiments by magnesium hydroxide at different pH values have been carried out by Liu et al. (2004), Fuente and Muñoz (2006) and Yuan et al. (2006). They attributed the adsorption of B(OH)$_4^-$ to the magnesium hydroxide. Their results showed that [B]$_{fsw}$ reached its lowest values at pH 9.3 or 10, which indicates that adsorption had reached its highest values. The [B]$_{fsw}$ then increased slowly at higher pH values. The results of the present study are consistent with their works.

There is a slight difference in the variation of [B]$_d$ with pH for different $T_r$ values. When $T_r = 0$ h and pH = 9.5, [B]$_d$ is slightly lower than that at pH 10, and the highest [B]$_d$ value of 937.8 ppm also appears at pH 10. But when $T_r = 20$ h, the maximum [B]$_d$ may appear at pH $\leq$ 9.5, while the highest value at pH 9.5 is 1859 ppm, which is much higher than 951.5 ppm at pH 10. Considering the slight difference in the boron balance time of the deposited Mg(OH)$_2$, the value for $T_r = 20$ h may be more reliable.

The evolution pattern of boron incorporated into the Mg(OH)$_2$, and the variations in partition coefficients with pH, are basically the same as those of oxides and clay minerals. However, the maximum amounts of incorporated boron in brucite or other
hydroxides are much higher than those of the oxides and clay minerals (Keren et al., 1981, 1983; Goldberg and Glaubig, 1985, 1986; Lemarchand et al., 2005, 2007), indicating the incorporation capacity of boron on hydroxides is stronger than that on both oxides and clay minerals.

3.3 Isotopic fractionation of boron between deposited brucite and solution

Isotopic compositions of boron in deposited brucite ($\delta^{11}B_d$) and final seawater ($\delta^{11}B_{fsw}$) are listed in Table 3 and shown in Fig. 3. The crucial points illustrated in Fig. 3 are summarized as follows:

1. The variation trend of the results for $T_r = 0\ h$ and $T_r = 20\ h$ are basically same (Fig. 3a). This indicates that the isotopic balance between brucite deposit and solution is instantaneous, and that the results of the experiment are exact. A minor difference between $T_r = 0\ h$ and $T_r = 20\ h$ appears at the pH increases from 9.5 to 10.0. When $T_r = 0\ h$, $\delta^{11}B_d$ and $\alpha_{d-fsw}$ both increase as the pH increases from 9.5 to 10.0. However, when $T_r = 20\ h$, $\delta^{11}B_d$ and $\alpha_{d-fsw}$ both decrease as the pH increases from 9.5 to 10.0. This is perhaps related to the fact that the formation of brucite is slower in low pH than in high pH.

2. All the $\delta^{11}B_d$ values are enriched in the heavy isotope relative to the $\delta^{11}B_{fsw}$ (Fig. 3a). All the $\alpha_{d-fsw}$ are greater than 1 (Fig. 3b), which is entirely different from those of the carbonates deposits (Fig. 3c). As $\text{B(OH)}_4^-$ is incorporated preferentially into carbonate deposits, all the $\delta^{11}B$ values of carbonates are lower than that of the parent seawater. Meanwhile, all the isotopic fractionation factors $\alpha_{\text{carb}-\text{sw}}$ between carbonates and seawater are lower than 1 and increase with pH. In this study, the $\alpha_{d-fsw}$ between brucite deposit and solution shows a waved pattern (Fig. 3b), suggesting a complex isotopic fractionation process.

The $\delta^{11}B_d$, $\delta^{11}B_{\text{isw}3}$ and $\delta^{11}B_{\text{isw}4}$ of $\text{B(OH)}_3$ and $\text{B(OH)}_4^-$ in initial seawater, calculated using the different $\alpha_{4-3}$ versus pH values of the parent solutions, are shown...
in Fig. 4. When $T_r = 0$ h, the $\delta^{11}B_d$ values are equal to or lower than the $\delta^{11}B_{isw3}$ calculated using $\alpha_{4-3} = 0.9600$. When $T_r = 20$ h, the $\delta^{11}B_d$ values are equal to or lower than the $\delta^{11}B_{isw3}$ calculated using $\alpha_{4-3} = 0.9397$, but all the $\delta^{11}B_d$ values are higher than $\delta^{11}B_{isw}$ (Fig. 4). The $\alpha_{4-3}$ of 0.9600 and 0.9397 is calculated according to the highest $\delta^{11}B$ of deposited brucite for $T_r = 0$ h and $T_r = 20$ h. If $\delta^{11}B_d$ is equal to $\delta^{11}B_{isw3}$, it implies that only B(OH)$_3$ is incorporated into Mg(OH)$_2$, which is impossible under normal circumstances. Moreover a situation in which $\delta^{11}B_d > \delta^{11}B_{isw3}$ would be even more improbable. Except for pH 9.5, $\delta^{11}B_d$ values are lower than $\delta^{11}B_{isw3}$ calculated using $\alpha_{4-3} = 0.9600$ (Fig. 4), so that the true $\alpha_{4-3}$ would have to be lower than 0.9600, which is a little lower than the currently expected value between 0.983 and 0.952 (Zeebe, 2005). The pH values used in previous carbonates precipitation experiments are lower than 9.0, while that of our experiments are between 9.5 and 13.0. The differences of the experiments conditions may result diverse $\alpha_{4-3}$, but which value is much more reliable or what is the true $\alpha_{4-3}$ is still uncertain. Our results also indicate that $\delta^{11}B_d$ is not parallel with $\delta^{11}B_{isw3}$, but first decreases and then increases with an inflexion at pH 12. All of the data indicate that both B(OH)$_3$ and B(OH)$_4^–$ are incorporated into the deposited brucite.

The fractions of B(OH)$_3$ ($F_{d3}$) in the brucite deposit calculated using $\alpha_{4-3} = 0.9397$ and $\alpha_{4-3} = 0.9600$ are shown in Fig. 5. It seems that $F_{d3}$ tends to decrease with decreasing $\alpha_{4-3}$. Because the adopted $\alpha_{4-3}$ is not true, the calculated $F_{d3}$ is not exact. The true $F_{d3}$ could be lower than the value indicated in Fig. 5, but the variation trend of $F_{d3}$ with pH should be certain and much higher than that of the initial artificial seawater ($F_{isw3}$). The $\delta^{11}B_d$ is the concurrent result of $\delta^{11}B_{d3}$ and $\delta^{11}B_{d4}$. Here $\delta^{11}B_d$ can be shown as:

$$\delta^{11}B_d = f_{d3} \times \delta^{11}B_{d3} + (1 - f_{d3}) \times \delta^{11}B_{d4}$$

(4)
where $f_{d3}$ is the fraction of B(OH)$_3$ in solid. During pH 10–12, both $\delta^{11}$B$_{d3}$ and $\delta^{11}$B$_{d4}$ increases with increasing pH (Fig. 1b). Therefore, the $\delta^{11}$B$_d$ should be increased with the increasing pH, but the increasing trend is inconspicuous (Fig. 3a). There are two reasons accounting for this. On the one hand, the increasing $\delta^{11}$B$_{d3}$ and $\delta^{11}$B$_{d4}$ can result in the increasing of $\delta^{11}$B$_d$. On the other hand, with the increasing pH, the dominant decreasing incorporation fraction of B(OH)$_3$ and increasing incorporation fraction of B(OH)$_4^-$ will result the deceasing of $\delta^{11}$B$_d$. With the common influence of these two aspects, the variation of $\delta^{11}$B$_d$ with pH is small. When pH reaches 12 (PZC of brucite), the adsorption quantity of B(OH)$_4^-$ decreases suddenly, while that of B(OH)$_3$ increases (Fig. 5). So the $\delta^{11}$B$_d$ increases.

3. The manner in which $\alpha_{d-fsw}$ changes with pH for $T_r = 0$ h and 20 h is shown in Fig. 3b. Except for pH 9.5, both patterns are basically the same for each $T_r$, and match the change in $F_{d3}$ shown in Fig. 5. The $\alpha_{d-fsw}$ values decrease as the pH increases from 9.5 to 12, and reach the lowest point at pH 12. Then $\alpha_{d-fsw}$ values increase rapidly. The $\alpha_{d-fsw}$ reflects the relative ratio of B(OH)$_3$ to B(OH)$_4^-$ in brucite.

The explanation of $\delta^{11}$B$_d$ with pH can be also used to the explanation of boron fractionation factor between brucite and solution. When pH from 10 to 12, incorporation fraction of B(OH)$_3$ decreases continuously (Fig. 5), and contrary is that of B(OH)$_4^-$ increases. This lead to the deceases ratio of B(OH)$_3$ to B(OH)$_4^-$, so the $\alpha_{d-sw}$ decreases. When pH reaches 12 (PZC of Mg(OH)$_2$), the adsorption quantity of B(OH)$_4^-$ decreases suddenly, and the relative ratio of B(OH)$_3$ to B(OH)$_4^-$ increases (Fig. 5), so the $\alpha_{d-fsw}$ also increases.

Our results indicate that B(OH)$_3$ is preferentially incorporated into the solid phase during the deposition of brucite. In a precipitated experiment of calcium carbonates from artificial seawater, Xiao et al. (2006) obtained the result that the boron isotopic
fractionation factors between calcium carbonates and seawaters were higher than 1. They reasoned that the presence of Mg$^{2+}$ or other microelements was the main reasons of this observation and concluded that the heavier B(OH)$_3$ species was incorporated preferentially into Mg(OH)$_2$. The results of our study further confirmed the conclusion of Xiao et al. (2006).

4 Model of boron incorporated into brucite

Model 1: boron adsorption by minerals

The boron adsorption by minerals can be explained by phenomenological equation (Keren et al., 1981). It is supposed that when B(OH)$_3$, B(OH)$_4^-$ and OH$^-$ coexist in solution, they can be adsorbed by Mg(OH)$_2$, metal oxides and clay minerals, and the affinity coefficients $K_{B3}$, $K_{B4}$ and $K_{OH}$ are $K_{B3} < K_{B4} < K_{OH}$ for B(OH)$_3$, B(OH)$_4^-$ and OH$^-$, respectively (Keren et al., 1981). They compete for the same adsorption site on solid. When pH is less than 7, B(OH)$_3$ is dominant. Because $K_{B3}$ to clay mineral is very low, the boron adsorption is relatively minor. Under this pH value, the concentration of B(OH)$_4^-$ and OH$^-$ is very low. Although they have relatively stronger affinity to clay, the contribution of them to the total boron adsorption is still very little. When pH increases to 9, B(OH)$_4^-$ concentration increases rapidly. Compared with B(OH)$_4^-$, OH$^-$ concentration is still lower. So the adsorbed boron increases rapidly. When pH further increases, OH$^-$ concentration will increase evidently, and the boron contribution decreases because of the competition for adsorption site with B(OH)$_4^-$. In this study when pH is lower than 10, $K_d$ increases as the pH increases (Fig. 2b). The $K_d$ reaches its highest values at pH 10. When pH is higher than 10, $K_d$ decreases and shows a mild trend after pH 12. The variation characteristics of $K_d$ with pH can also be explained partly by this model. But isotopic fractionation characteristics of boron, the maximum adsorption value and $K_d$ value of brucite deposit can not be explained by this totally.
The incorporation of $\text{B(OH)}_4^-$ into brucite is may be related with adsorption. Previous studies (Liu et al., 2004; Garcia-Soto and Camacho, 2006; Yuan et al., 2006) have indicated that the incorporation of boron into brucite or MgO was an adsorption process. When $\text{Mg}^{2+}$ exists in solution, it can be adsorbed by brucite crystallite, and the resulting positive charge can adsorb the negatively charged $\text{B(OH)}_4^-$. The equation is shown as follows:

$$\left\{ [\text{Mg(OH)}_2]_m \cdot n\text{Mg}^{2+} \right\}^{2n+} + x\text{B(OH)}_4^- \rightarrow \left\{ [\text{Mg(OH)}_2] \cdot n\text{Mg}^{2+} \cdot x\text{B(OH)}_4^- \right\}^{2n-x} \downarrow \quad (5)$$

If model 1 is applied, the $\delta^{11}\text{B}_d$ should be lower than $\delta^{11}\text{B}_{isw}$ and $\alpha_{d-sw}$ should be lower than 1. In this study, however, the results show that all $\delta^{11}\text{B}_d$ are higher than $\delta^{11}\text{B}_{isw}$ and $\alpha_{d-sw}$ values are higher than 1. This suggests that the model 1 is not suitable to explain all the data in our study.

The apparent pH dependence of the fractionation between carbonates and clays can be described in terms of the $\alpha_{3-4}$ and the $pK_a$ of the boric acid-borate equilibrium (Sanchez-Valle et al., 2005). This model explains the B isotopic fractionation data for inorganically and biologically precipitated carbonates and clays, and suggests that in minerals like clay and other layered hydroxides, surface charge properties play an important role by changing the apparent acid-base equilibrium constant.

In our study, $pK_a$ of the boric acid-borate equilibrium may be affected due to the presence of positive charge on the Mg(OH)$_2$ surface. The fraction and $\delta^{11}\text{B}$ of boron species calculated using different $pK_a$ versus pH values is shown in Fig. 6, which suggests that the influence of $pK_a$ on fraction and $\delta^{11}\text{B}$ of boron species is big for solution with pH < 10. When pH > 10, the influence of $pK_a$ is insignificant. For example, the $\delta^{11}\text{B}_{isw}$ calculated using $pK_a$ 7.0, 8.0 and 9.0 ($\alpha_{4/3} = 0.975$) are 16.08‰, 5.57‰ and −4.74‰, respectively for pH 8, and 18.44‰, 18.21‰ and 15.89‰, respectively for pH 10. When pH > 11, there are basically no differences among them. The pH values of our experiments are higher 10, so the isotopic fractionation characteristics of boron do not attributed to the change of $pK_a$. 

901
Model 2: chemical reaction of B(OH)_3 with Mg(OH)_2

Rodionov et al. (1991) reported that when limewater was added to seawater, CaO·B_2O_3·nH_2O was deposited. This reaction is shown as follows:

$$2 \text{H}_3\text{BO}_3 + \text{Ca(OH)}_2 + \text{aq} \rightarrow \text{CaO} \cdot \text{B}_2\text{O}_3 \cdot \text{nH}_2\text{O} + \text{aq}$$

During deposition of brucite, a similar reaction may occur. MgO·B_2O_3·nH_2O may also be deposited. This hypothesis was confirmed by the XRD analyses of brucite. Compared with Fig. 7a, the brucite peak in Fig. 8 is clear, with apparent peaks of pinnoite (Mg(BO_2)_2·3H_2O) and szaibelyite (MgBO_2(OH)). Judged from quantity and intensity of these peaks, pinnoite content should be higher than that of szaibelyite. As pH increases, the borate peak gradually weakens (Fig. 7b–g). When pH is 12.5 (Fig. 7g), its peak is very close to that of Mg(OH)_2, though the characteristic pinnoite peak is still observed. The pinnoite is the result of the following reaction between brucite and H_3BO_3:

$$2 \text{H}_3\text{BO}_3 + \text{Mg(OH)}_2 \rightarrow \text{Mg(BO}_2)_2 \cdot 3 \text{H}_2\text{O} + \text{H}_2\text{O}$$

The above reaction cannot occur for B(OH)_4. So F_{d3} can exceed F_{fsw3} due to the preferential incorporation of H_3BO_3 into Mg(OH)_2, which enriches the deposited brucite in ^{11}B. The presence of szaibelyite may be the result of B(OH)_4 adsorption.

If model 2 is applied, the δ^{11}B_d should be higher than δ^{11}B_{fsw} and α_{d–fsw} values should higher than 1. Furthermore, δ^{11}B_d and α_{d–fsw} should decreases with increasing pH values. In our study, all the δ^{11}B_d values are enriched in the heavy isotope compared relative to the δ^{11}B_{fsw} (Fig. 3a), and all the α_{d–fsw} are greater than 1 (Fig. 3b), which are consistent with model 2. But the α_{d–fsw} shows a waved pattern (Fig. 3b), which indicates a complex isotopic fractionation process and can not be explained completely by model 2.

The fraction of boric acid in solution is negligible at high pH values (Fig. 1a), so that the B(OH)_3 incorporated into brucite should be little. But the F_{d3} is much higher than...
the $F_{\text{sw3}}$ (Fig. 5). This may be related with the transformation of borate to boric acid. After $\text{B(OH)}_3$ is incorporated into brucite, $F_{\text{sw3}}$ decreases. In order to keep balance of $\text{B(OH)}_3/\text{B(OH)}_4^-$ ratio, $\text{B(OH)}_4^-$ in solution would transform to $\text{B(OH)}_3$. Meanwhile, the total boron quantity in solution decreases compared with initial solution. When a new equilibrium reaches, $\text{B(OH)}_3$ continues to incorporate into brucite, and $\text{B(OH)}_4^-$ in solution will transform to $\text{B(OH)}_3$ to keep the equilibrium. This process will repeat, and finally the $F_{\text{d3}}$ is much higher than the $F_{\text{sw3}}$. But the total boron quantity in solution is much less than that in the initial solution.

Model 3: both chemical reaction and adsorption of boron incorporated into brucite

Many studies have indicated that only $\text{B(OH)}_4^-$ is incorporated preferentially into marine carbonates (Vengosh et al., 1991; Hemming et al., 1992, 1995; Spivack et al., 1993; Sanyal et al., 1995, 1996, 1997, 2000). Under this circumstance, all the $\delta^{11}\text{B}$ values of carbonates are considered to be paralleled with the theoretical $\delta^{11}\text{B}_{\text{sw3}}$ and are lower than that of the parent seawater; $\alpha_{\text{carb}-\text{sw}}$ between carbonates and seawater are lower than 1 and increase with pH. When boron is adsorbed by oxides or clay minerals, the adsorption ability of $\text{B(OH)}_4^-$ is much stronger than that of $\text{B(OH)}_3$. The $\text{B(OH)}_4^-$ is also incorporated preferentially into oxides or clay minerals, causing the enrichment of $^{10}\text{B}$ in oxides or clay minerals. Our results show that $\delta^{11}\text{B}_{\text{d}}$ is higher than $\delta^{11}\text{B}_{\text{sw}}$ and parallels neither with $\delta^{11}\text{B}_{\text{sw4}}$ nor with $\delta^{11}\text{B}_{\text{sw3}}$, but changes from decreases to increase with an inflexion at pH 12 (Fig. 3b). This indicates that both $\text{B(OH)}_4^-$ and $\text{B(OH)}_3$ are incorporated into brucite, and the latter is incorporated into brucite preferentially. Boron incorporation into brucite may be controlled by two processes: chemical reaction of $\text{B(OH)}_3$ with brucite and $\text{B(OH)}_4^-$ adsorption onto brucite. The simultaneous occurrence of these two processes decides the boron concentration and isotopic fractionation of brucite. The mechanisms of boron incorporated into brucite are distinct from those of carbonates and oxides or clay minerals.
5 The influence of brucite on isotopic composition of boron in corals

Brucite exists in a wide range of common reef-building coral in Great Barrier Reef and Florida (Nothdurft et al., 2005). Fortunately, the brucite in older corals was lack due to being dissolved in seawater, where it is undersaturated (Nothdurft et al., 2005). Inadvertent sampling of corals containing brucite could be responsible for anomalies Mg/Ca vs. SST plots in corals. Many studies have shown that \( \text{B(OH)}_4^- \) is the dominant species incorporated into corals or foraminifers and \(^{10}\text{B}\) enrich in corals (Vengosh et al., 1991; Hemming and Hanson, 1992; Spivack et al., 1993; Sanyal et al., 1995, 1996, 1997), but Klochko et al. (2009) found that both trigonal and tetrahedral coordinated boron existed in biogenic and hydrothermal carbonates. The occurrence of brucite in coral may change the isotopic composition of boron in coral due to the heavier \( \text{B(OH)}_3^- \) species is incorporated preferentially into brucite and the deviant high boron isotopic composition of corals may associate with the occurrence of brucite. An exploratory study on the influence of brucite on the boron isotopic composition in modern corals is justifiable.

6 Conclusions

Based on the above experimental results, the following conclusions can be drawn:

1. Boron concentration of deposited brucite and partition coefficient \( K_d \) between deposited brucite and resultant seawater is controlled by pH of solution. The incorporation capacity of boron into brucite is much stronger than that into oxides and clay minerals.

2. All the \( \delta^{11}\text{B}_d \) values are higher than \( \delta^{11}\text{B}_{fsw} \) and all the fractionation factors \( \alpha_{d-fsw} \) are higher than 1, indicating the preferential incorporation of \( \text{H}_3\text{BO}_3 \) into \( \text{Mg(OH)}_2 \). The mechanism of boron incorporated into brucite is distinct from that of carbonates deposition.
3. During deposition of brucite, both $\text{H}_3\text{BO}_3$ and $\text{B(OH)}_4^-$ incorporated into brucite. The simultaneous occurrences of boron adsorption onto brucite and precipitation reaction of $\text{H}_3\text{BO}_3$ with brucite decide the boron concentration and isotopic fractionation of the resulting brucite.

4. The isotopic compositions of boron in modern corals might be affected by both the existence of brucite in madrepore and the preferential incorporation of $\text{B(OH)}_3$ into brucite. An exploratory study on the influence of brucite on the boron isotopic composition in modern corals is justifiable.
