Abstract. We have constructed a regional tree ring cellulose oxygen isotope (δ18O) record for the northern Indian subcontinent based on two new records from north India and central Nepal and three published records from Northwest India, western Nepal and Bhutan. The record spans the interval from 1743-2008 CE. Correlation analysis reveals that the record is significantly negatively correlated with the three regional climatic indices: All India Rainfall (r = -0.5, p <0.001, n =138), Indian monsoon index (r = -0.45, p <0.001, n =51) and the intensity of monsoonal circulation (r = -0.42, p <0.001, n =51). The close relationship between tree ring cellulose δ18O and the Indian summer monsoon (ISM) can be explained by oxygen isotope fractionation mechanisms. Our results indicate that the regional tree ring cellulose δ18O record is suitable for reconstructing high-resolution changes in the ISM. The record exhibits significant inter-annual and centennial variations. Inter-annual changes are closely related to the El Niño-Southern Oscillation (ENSO), which indicates that the ISM was affected by ENSO in the past. However, the ISM-ENSO relationship was not consistent over time. Centennial changes in the regional tree ring δ18O record indicate a trend of weakened ISM intensity since 1820. Decreasing ISM activity is also observed in various high-resolution ISM records from southwest China and Southeast Asia, and may be the result of reduced land-ocean thermal contrasts since 1820 CE.

1 Introduction

The Indian summer monsoon (ISM) delivers a large amount of summer precipitation to the Indian continent, and thus has a major influence on economic activity and society in this densely-populated region (Webster et al., 1998). Current research on
the ISM is mainly concerned with the study of inter-annual and inter-decadal variations, using meteorological data and climate models. The ISM is affected by the El Niño-Southern Oscillation (ENSO) (Kumar et al., 1999; Kumar et al., 2006; Webster et al., 1998), North Atlantic SST (Goswami et al., 2006; Kripalani et al., 2007), atmospheric carbon dioxide concentration (Kripalani et al., 2007), aerosol concentrations (Bollasina and Ramaswamy, 2011) and solar activity (Hiremath et al., 2015) on different time scales. A good understanding of mechanisms driving ISM change on different time scales could help to predict possible changes of ISM in the future. However, the observed meteorological records are too short to assess centennial changes in ISM. Therefore, long-term proxy records of ISM are needed.

The abundance of *Globigerina bulloides* in marine sediment cores from the Arabian Sea indicated a trend of increasing ISM strength during the last 400 years (Anderson et al., 2002). However, oxygen isotopes in tree-rings and ice cores from the Tibetan Plateau revealed a weakening trend ISM since 1840 or 1860 (Duan et al., 2004; Grießinger et al., 2016; Liu et al., 2014; Wernicke et al., 2015). In addition, a stalagmite oxygen isotope record from northern India indicated that the ISM experienced a 70-year pattern of variation over the last 200 years, with no clear trend (Sinha et al., 2015). Since there are spatial differences in the patterns of climate change in monsoonal areas (Sinha et al., 2011), geological records with a wide distribution are needed. In addition, the climate proxies used should be closely related to the ISM and the records need to be well-replicated and accurately dated.

Available tree ring records are widely distributed in the Indian monsoon region (Yadav et al., 2011). The climate of the southern Himalayas is dominated by changes in the Indian summer monsoon, and is therefore the region is well suited to the study of Indian monsoon variations. The oxygen isotopic composition ($\delta^{18}$O) of tree rings is mainly controlled by the $\delta^{18}$O of precipitation and by relative humidity (Ramesh et al., 1985; Roden et al., 2000), and both are affected by the Indian summer monsoon (Vuille et al., 2005). Compared with tree ring width data, tree ring $\delta^{18}$O records are more suited to retrieving low-frequency climate signals, and therefore they have the ability to record the Indian summer monsoon (Gagen et al., 2011; Sano et al., 2011; Sano et al., 2013). However, a local record may not be fully representative of changes in the ISM.

Consequently, we combined several tree ring $\delta^{18}$O records from the ISM region. Two new records from northern India and
central Nepal were obtained in this study, and were combined with three previously published records from northwest India, western Nepal and Bhutan (Sano et al., 2011; Sano et al., 2013; Sano et al., submitted) The data were integrated in order to produce a regional tree ring δ¹⁸O record which was used to reconstruct the history of the ISM during the last few hundred years, and to investigate its possible driving mechanisms on various time scales.

2 Materials and methods

2.1 Sampling sites

Five tree ring cellulose δ¹⁸O records were selected to construct a regional climate signal for the southern Himalaya (Figure 1). Three records (Manali, in northwest India; Humla, in west Nepal; and Wache, in Bhutan) were published previously (Sano et al., 2011; Sano et al., 2013; Sano et al., submitted). Two tree ring cellulose δ¹⁸O chronologies were constructed in this study. Core samples for Cedrus deodara near Jageshwar (29°38'N, 79°51'E, 3849 m a.s.l., JG) and Abies spectabilis near Ganesh (28°10'N, 85°11'E, 3550 m a.s.l.) were collected in 2009 and 2001, respectively. Information about each sampling site is shown in Table 1. In general, two core samples for each tree were collected at breast height using a 5-mm diameter increment corer. The cores were air dried at room temperature for 2-3 days and the surfaces were then smoothed with sand paper to render the ring boundaries clearly visible. The ring widths of the samples were measured at a resolution of 0.01mm using a binocular microscope with a linear stage interfaced with a computer (Velmex™, Acu-Rite). Cross dating was performed in the laboratory by matching variations in ring width from all cores to determine the absolute age of each ring. Quality control was conducted using the COFECHA computer program (Holmes, 1983).

2.2 Cellulose extraction and isotope measurements

Four trees near Ganesh and three trees near Jageshwar, all with relatively wide rings, were selected for oxygen isotope analysis (Figures 2 & 3). The modified plate method (Xu et al., 2011; Xu et al., 2013b, Kagawa et al., 2015), based on the chemical treatment procedure of the Jayme-Wise method (Green, 1963; Loader et al., 1997), was used to extract α-cellulose. The plate method of extracting α-cellulose directly from the wood plate rather than from individual rings can reduce the α-cellulose extraction time (Xu et al., 2011). In addition, the modified plate method can reduce the amount of sample material
lost during cellulose extraction, enabling sufficient material to be obtained to enable narrow rings to be measured by isotope ratio mass spectrometer (Xu et al., 2013). There is no statistically significant difference between tree ring $\delta^{18}O$ values obtained by the plate and conventional methods (Kagawa et al., 2015; Xu et al., 2013b).

Cellulose samples (sample weight, 120-260 µg) were wrapped in silver foil, and tree ring cellulose oxygen isotope ratios ($^{18}O/^{16}O$) were measured using an isotope ratio mass spectrometer (Delta V Advantage, Thermo Scientific) interfaced with a pyrolysis-type high-temperature conversion elemental analyzer (TC/EA, Thermo Scientific) at the Research Institute for Humanity and Nature, Japan. Cellulose $\delta^{18}O$ values were calculated by comparison with Merck cellulose (laboratory working standard), which was inserted after every eight tree samples during the measurements. Oxygen isotope results are presented using the $\delta$ notation as the per mil (‰) deviation from Vienna Standard Mean Ocean Water (VSMOW): $\delta^{18}O = \left[\left(\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1\right) \times 1000\right]$, where $R_{\text{sample}}$ and $R_{\text{standard}}$ are the $^{18}O/^{16}O$ ratios of the sample and standard, respectively. The analytical uncertainty for repeated measurements of Merck cellulose was approximately ±0.15‰.

2.3 Meteorological data and climate analyses

In the northern Indian subcontinent, the monsoon season is from June to September. The summer monsoon season supplies 78% and 83% of the annual precipitation for Kathmandu and New Delhi, respectively. The Indian monsoon index (IMI) (Wang et al., 2001), the intensity of monsoon circulation (Webster and Yang, 1992) and All India Rainfall (AIR, obtained from the Indian Institute of Tropical Meteorology, Pune, India) were selected as proxies for the Indian summer monsoon in order to investigate the relationship between tree ring cellulose $\delta^{18}O$ variations and the monsoon. In addition, we used the Royal Netherlands Meteorological Institute Climate Explorer (http://www.knmi.nl/) to determine spatial correlations between tree-ring cellulose $\delta^{18}O$, precipitation (GPCC V7) and sea-surface temperature (SST) values obtained from the National Climatic Data Center v4 data set. Temperature reconstructions for the Indian Ocean (Tierney et al., 2015) and the Tibetan Plateau (Shi et al., 2015), spanning the last 400 years, were used to obtain a record of the history of land-ocean thermal contrast.
3 Results and discussion

3.1 Tree ring $\delta^{18}O$ variations in the southern Himalaya and a regional tree ring $\delta^{18}O$ record

The oxygen isotopes of four individuals of *Abies spectabilis* in Ganesh (GE, central Nepal) and three individuals of *Cedrus deodara* in Jageshwar (JG, northern India) were measured for the interval from 1801-2000 CE and 1643-2008 CE, respectively. Individual tree ring $\delta^{18}O$ time series from four cores from central Nepal are shown in Figure 2a. The mean values of the $\delta^{18}O$ time series from 224c, 233b, 235b, and 226a are 23.09‰, 22.66‰, 21.87‰, and 22.94‰, respectively, from 1901-2000 CE; the standard deviations are 1.22‰, 1.27‰, 1.12‰, and 1.42‰, respectively. The inter-tree differences in $\delta^{18}O$ values are small. The $\delta^{18}O$ values of the four cores exhibit peaks in 1813. The mean inter-series correlations (Rbar) among the cores range from 0.56 - 0.78 (Figure 2c), based on a 50-year window over the interval from 1801-2000 CE.

Three tree ring $\delta^{18}O$ time series from northern India (JG) are shown in Figure 3a. The mean values of the $\delta^{18}O$ time series from 101c, 102c, and 103a are 30.11‰, 29.7‰, and 29.47‰, respectively, over the interval from 1694-2008 CE; the standard deviations are 1.49‰, 1.62‰ and 1.53‰, respectively. Three tree ring $\delta^{18}O$ time series in JG exhibit a consistent pattern of variations. The mean inter-series correlations (Rbar) among the cores range from 0.61-0.78 (Figure 3c), based on a 50-year window over the interval from 1641-2008 CE.

We combined our data with three previously published tree ring $\delta^{18}O$ chronologies from northwest India, eastern Nepal and Bhutan (Sano et al., 2011; Sano et al., 2013; Sano et al., submitted) to construct a regional tree ring $\delta^{18}O$ record. Although multi-decadal changes in five tree ring $\delta^{18}O$ chronologies are not always identical during the entire study interval, the five tree ring $\delta^{18}O$ records for the Himalaya region are significantly correlated (Table 2). This indicates that they reflect a common controlling factor that may be related to regional climate. The five $\delta^{18}O$ records were individually normalized over the interval from 1801-2000 CE, and then averaged to produce a regional Himalayan $\delta^{18}O$ record (H5 $\delta^{18}O$ record) for the entire interval (Figure 4). Only one chronology (JG) spans an interval prior to 1742 CE, and therefore we focus on the interval from 1743-2008 CE in this study.
3.2 Climatic signals in the regional tree ring δ¹⁸O chronology

An earlier study showed that tree cellulose δ¹⁸O in eastern Nepal (Humla) recorded June-September PDSI changes in the last 200 years (Sano et al., 2011), and Sano et al. (2013) reconstructed a record of May-September precipitation using a tree ring δ¹⁸O record (JG) from Bhutan for the interval from 1743-2011 CE. A recent tree ring δ¹⁸O record from northwest India (Manali) is significantly correlated with June-September precipitation/PDSI. The two new tree ring δ¹⁸O records obtained in the present study (JG and Ganesh) are negatively correlated with June-September PDSI in northern India. Based on these findings, we conclude that the regional tree ring δ¹⁸O record (H5) should reliably record regional changes in moisture during the monsoon season.

Previous studies have used the intensity of atmospheric circulation and the rainfall of the whole of India to reflect the intensity of the ISM (Mooley and Parthasarathy, 1984; Wang et al., 2001; Webster and Yang, 1992). We assessed the potential of the H5 δ¹⁸O record as an indicator of past monsoon changes by correlating it with All India Rainfall (AIR), the Indian Monsoon Index (IMI) and the intensity of monsoon circulation. The results revealed a significant negative correlation with AIR \( (r = -0.5, p <0.001, n =138) \), IMI \( (r = -0.45, p <0.001, n =51) \) and the intensity of the monsoon circulation \( (r = -0.42, p <0.001, n =51) \) (Figure 5). In addition, the results of spatial correlation analyses reveal that the H5 δ¹⁸O record is negatively correlated with gridded June-September precipitation in northwest and northern India and Nepal (Figure 6). These findings indicate that the H5 δ¹⁸O record is capable of reflecting ISM changes from a statistical perspective.

Tree ring δ¹⁸O has a close relationship with the ISM based on tree ring cellulose oxygen isotope fractionation model. Precipitation δ¹⁸O and relative humidity are the two main factors controlling tree ring δ¹⁸O (Roden et al., 2000), and both are related to ISM changes in the monsoonal area. There is a negative correlation between the ISM and precipitation δ¹⁸O in the monsoonal area (Vuille et al., 2005; Yang et al., 2016). Asian summer monsoon affects the δ¹⁸O of precipitation through the amount effect (Cai and Tian, 2016; Lekshmy et al., 2015; Dansgaard, 1964). A stronger summer monsoon usually brings more summer rainfall to the southern Himalaya. The removal of the heavier isotopes during the condensation process results in the oxygen isotopic depletion of the water vapor. The greater the total amount of precipitation, and the stronger the
convection, the more the oxygen isotopic composition of the rainwater is affected by depletion (Lekshmy et al., 2014; Vuille et al., 2003), and this signal is reflected in tree ring δ¹⁸O values. On the other hand, a stronger ISM leads to higher relative humidity, and a lower re-evaporation rate for rainfall or a reduced evaporation of leaf water in trees, resulting in less enriched tree ring δ¹⁸O values (Risi et al., 2008; Roden et al., 2000).

3.3 Interannual to centennial variability of the ISM inferred from the regional tree ring δ¹⁸O record

The results of spectral analysis using the multi-taper method (Mann and Lees, 1996) indicates that the H5 regional tree ring δ¹⁸O record contains several high-frequency quasi-periodicities (2.4, 4 and 5 years), as well as lower frequency periodicities (160–350 years) at a confidence level greater than 99% (Figure 7). This indicates that interannual and centennial variability of the ISM was dominant characteristic feature during the last several hundred years. The interannual variability (2-5 years) of the H5 record is similar to that of ENSO, suggesting a possible relationship (Mason, 2001). The spatial correlation between the H5 record and SST also reveals a close relationship between the ISM and ENSO (Figure 8). Other high-resolution ISM-related records from monsoonal Asia also exhibit similar inter-annual periodicities (Sun et al., 2016; Xu et al., 2013a; Yadava and Ramesh, 2007). In addition, meteorological data indicates that ENSO has had a significant influence on changes in the ISM change since 1870 CE (Kumar et al., 1999; Webster et al., 1998).

However, observational data indicate that the ENSO-ISM relationship is not consistent over time because of the southeastward shift of the descending limb of the Walker circulation and the varying monsoonal impact of the different patterns of El Niño (Kumar et al., 1999; Kumar et al., 2006). Thirty-one-year running correlations between the H5 regional tree ring δ¹⁸O record and two reconstructed ENSO indices (McGregor et al., 2010; Wilson et al., 2006) reveal that this type of unstable ISM-ENSO relationship occurred during the last 250 years (Figure 9). The reason may be that the two different patterns of El Niño (eastern-Pacific and central-Pacific) yield different monsoon impacts (Kumar et al., 2006). In addition, other factors, such as the Indian Ocean Dipole, also influence the ISM (Abram et al., 2008).
Most proxy-based ENSO reconstructions focused on canonical El Niño events (eastern-Pacific El Niño) are characterized by unusually warm sea surface temperatures (SST) in the eastern equatorial Pacific (Gergis and Fowler, 2009; Li et al., 2011; McGregor et al., 2010); while a different type of El Nino (central-Pacific El Nino) is characterized by warm SSTs in the central Pacific, flanked by cooler SSTs to the west and east. The latter is termed El Niño Modoki or the central-Pacific El Niño (Ashok et al., 2007; Kao and Yu, 2009; Yeh et al., 2009), and it has a different effect on the ISM (Kumar et al., 2006).

In order to characterize in detail the relationship between the ISM and the two types of ENSO during the last several hundred years, long-term coral-based records from the tropical eastern and central Pacific are needed. However, such high-resolution, continuous and robust SST reconstructions are scarce. Even in the equatorial Pacific ‘centre of action’ (COA) of ENSO, the COA SST reconstruction is not to be considered robust prior to 1850 CE (Wilson et al., 2010). A new eastern Pacific SST record for the last 400 years is not reliable during the interval from 1635-1702 CE and 1840-1885 CE (Tierney et al., 2015). The future availability of longer, annually resolved marine records that provide independent estimates of SSTs in the tropical Pacific will improve our understanding of the relationship between the ISM and the two types of ENSO.

The H5 regional tree ring δ18O record does not exhibit significant decadal to multi-decadal periodicities (Figure 7), while the main spectral component of high-resolution speleothem δ18O records (a proxy of ISM rainfall in northern and central India) consists of multi-decadal periodicities (~15, 20, 30, 60 and 70 years) (Sinha et al., 2011; Sinha et al., 2015). This inconsistency may be the result of the different types of proxy record used together with micro-environmental differences between the sampling sites. Although decadal to multi-decadal variability of the H5 tree ring δ18O record is not strongly developed, the record does contain decadal to multi-decadal changes. Decadal to multi-decadal variability was extracted using bandpass filters (15-80 years) (Figure 10, red line). From the perspective of decadal to multi-decadal changes, the H5 record shares similarities with the speleothem record, which indicates that they both record a common signal that is likely to be the ISM (Figure 10). Based on the oxygen isotope fractionation theory, tree ring δ18O and speleothem δ18O should share similar changes (Managave, 2014) if both of them inherit a common source water δ18O signal, as shown by Ramesh, et al (2013). The decadal to multi-decadal tree ring δ18O changes of the five records are out-of-phase with speleothem δ18O records during several intervals, which may be because samples were derived from different sites: H5 regional tree ring δ18O
chronology was composed of five tree ring $\delta^{18}$O time series from northwest India to Bhutan, while speleothem $\delta^{18}$O record located in northern India (Sinha et al., 2015). In addition, other factors differentially affect tree ring $\delta^{18}$O and speleothem $\delta^{18}$O values. Relative humidity has an important impact on tree ring $\delta^{18}$O in regions where the variation of relative humidity during the growing season exceeds 1%, while the mixing of infiltrating water from different rainfall events in the cave epikarst could result in a different source water $\delta^{18}$O signal for speleothems (Managave, 2014). Long-term process-based study on tree ring $\delta^{18}$O and speleothem $\delta^{18}$O variations in future study are needed for a better understanding for climatic implication of two proxies.

There are also significant centennial-scale variations in the H5 record (Figure 7), which were extracted using a 100-year low-pass filter (Figure 11, red line). The record exhibits a decreasing trend from 1743 to 1820 CE and an increasing trend since 1820 CE, which indicates a weakening trend of the ISM during the interval from 1820-2000 CE. A reduction in the monsoon precipitation/relative humidity of the ISM in the last 200 years is also evident in other areas influenced by the ISM. Maar lake sediments in Myanmar exhibit a decreasing trend of monsoonal rainfall since 1840 CE (Sun et al., 2016); a tree ring $\delta^{18}$O record from southeast Asia exhibits a drying trend since 1800 CE (Xu et al., 2013a); a stalagmite $\delta^{18}$O record from southwest China reveals an overall decreasing trend in monsoon precipitation since 1760 CE (Tan et al., 2016); and in southwest China, tree ring $\delta^{18}$O and maar lake records indicate reduced monsoon precipitation/relative humidity/cloud cover since 1840 or 1860 CE (Chu et al., 2011; Grießinger et al., 2016; Liu et al., 2014; Wernicke et al., 2015; Xu et al., 2012). However, in contrast, marine sediment records from the Western and Southeastern Arabian Sea exhibit an increasing trend of ISM strength over the last four centuries (Anderson et al., 2002; Chauhan et al., 2010). In addition, a recent study indicated that the contrasting trends in the ISM during the last several hundred years observed in geological records resulted from the different behavior of the Bay of Bengal branch and Arabian Sea branch of the ISM (Tan et al., 2016). However, the tree ring $\delta^{18}$O record in northwest India, influenced by the Arabian Sea branch of the ISM, exhibits a drying trend since 1950 CE (Sano et al., submitted), which does not support the idea of a strengthening ISM (Anderson et al., 2002). Moreover, there are no calibrated radiocarbon dates for the last 300 years for the two records from the Arabian Sea (Anderson et al., 2002a;
Chauhan et al., 2010). We suggest that further high-resolution and well-dated ISM records from western India are needed to improve our understanding of the behavior of the ISM.

The H5 record suggests a decreasing trend of ISM strength, which is supported by most of the other well-dated and high-resolution ISM records. A previous study has indicated that solar irradiance has a significant influence on the ISM on multi-decadal to centennial timescales, and that reduced solar output is correlated with weaker ISM winds (Gupta et al., 2005). However, solar irradiance has increased since 1810-1820 CE (Bard et al., 2000; Lean et al., 1995) and therefore it cannot be the main reason for the weaker ISM since 1820 CE. Atmospheric CO$_2$ content is another forcing factor for the ISM, with higher atmospheric CO$_2$ content resulting in a stronger ISM (Kripalani et al., 2007; Meehl and Washington, 1993). Thus, the increased atmospheric CO$_2$ content during the last 200 years is unlikely to be the reason for the weakened ISM. Several studies show that increased Indian Ocean SSTs caused a reduction in ISM rainfall (Fan et al., 2009; Naidu et al., 2009; Sun et al., 2016; Roxy et al, 2015). The Indian Ocean SST has increased since 1840-1860 CE (Tierney et al., 2015; Wilson et al., 2006), which supports this explanation. Although the SST of the Indian Ocean significantly affects the ISM, the land-sea thermal contrast is also an important influencing factor (Roxy et al., 2015). In particular, heating anomalies over the Tibetan Plateau have a significant influence on the ISM via their effect on the atmospheric temperature gradient between the Plateau and the tropical Indian Ocean (Bansod et al., 2003). Temperature differences between the Tibetan Plateau and the Indian Ocean were used to evaluate the history of land-sea thermal contrasts, and centennial variations in this record are shown in Figure 11b. The H5 record exhibits a similar pattern of changes on a centennial scale. The decreasing land-sea thermal contrast since 1820 CE has resulted in a weaker ISM, and the increasing trend of the H5 record since 1820 CE also indicates a reduced ISM intensity. The land-sea thermal contrast increased from 1880 to 1930 CE, while the intensity of the ISM inferred from the H5 record continued to weaken, which may be related to anthropogenic aerosol emissions. Aerosol emissions have resulted in a slowdown of the tropical meridional overturning circulation, cooler temperatures over Europe and Asia relative to the ambient oceans, and a corresponding weakening of the ISM circulation (Bollasina et al., 2011; Cowan and Cai, 2011).
4 Conclusions

We have combined three published tree ring cellulose $\delta^{18}$O records (from Northwest India, western Nepal and Bhutan) with two new tree ring cellulose $\delta^{18}$O records (from northern India and central Nepal) to produce a regional record (H5) for the northern Indian sub-continent for the interval from 1743-2008 CE. This record is significantly negatively correlated with All India Rainfall ($r = -0.5$, $p < 0.001$, $n = 138$), the Indian monsoon index ($r = -0.45$, $p < 0.001$, $n = 51$) and the intensity of the monsoon circulation ($r = -0.42$, $p < 0.001$, $n = 51$). Spatial correlation analysis indicates that the H5 record is negatively correlated with June-September precipitation in the northern Indian sub-continent. The Indian summer monsoon (ISM) controls the tree ring cellulose $\delta^{18}$O record via its effects on the $\delta^{18}$O of precipitation and relative humidity. Based on the observed statistical relationships and the physical mechanisms linking variations in tree ring $\delta^{18}$O and the ISM, regional tree ring cellulose $\delta^{18}$O chronology in the northern Indian sub-continent is a suitable high-resolution proxy for past ISM changes.

Inter-annual and centennial variations are evident in the regional tree ring $\delta^{18}$O chronology. Significant correlations between inter-annual changes and the El Niño-Southern Oscillation (ENSO) indicate that the ISM was affected by ENSO; however, this relationship was not consistent in the past. A robust, high-resolution and continuous ENSO reconstruction from the ‘centre of action’ area of the Pacific would shed more light on this relationship. Centennial-scale variations in the H5 record reveal a trend of weakened ISM intensity since 1820 CE, which is also evident in various high-resolution ISM records from southwest China and Southeast Asia. Reduced land-ocean contrasts since 1820 CE (Roxy et al., 2015), together with increased anthropogenic aerosol emissions during the last hundred years, may have contributed to the weakened ISM.

Figure 1. Map of the subcontinent showing tree-ring sites and color coded climatological monsoon precipitation from June to September. Insets show climatology of monthly precipitation at Kathmandu and New Delhi.
Figure 2. a: Tree ring $\delta^{18}O$ series of four individual trees: b: age profile, c: running EPS and Rbar statistics used 50-year windows and a 25-year lag for samples near Ganesh, Nepal.
Figure 3. a: Tree ring δ¹⁸O series for three individual trees: b: Age profile, c: running EPS and Rbar statistics using 50-year windows and a 25-year lag for samples near Jageshwar, India.
Figure 4. a: Five tree ring $\delta^{18}$O series from the southern Himalayas: b: Regional tree ring $\delta^{18}$O record (H5).
Figure 5. Comparison of the H5 regional tree ring $\delta^{18}O$ chronology with the All India Rainfall (a) and Indian Monsoon Index (b).
Figure 6. Spatial correlations between the H5 regional tree ring δ¹⁸O record with June-September precipitation from GPCC V7 over interval from 1901-2008 CE. Only correlations significant at the 95% level are shown.
Figure 7. Multi-taper power spectra for the H5 regional tree ring $\delta^{18}O$ record.
Figure 8. Spatial correlations between the H5 regional tree ring $\delta^{18}O$ record with May-September SST over the interval from 1871-2008 CE. Only correlations significant at the 95% level are shown.
Figure 9. 31-year running correlation between the H5 regional tree ring δ18O record and two reconstructed ENSO indices.
Figure 10. Comparison between multi-decadal regional tree ring $\delta^{18}O$ variations with stalagmite $\delta^{18}O$ changes in northern India.
Figure 11. a: Temperature reconstruction for the Tibetan Plateau and the Indian Ocean; b: centennial variations of the H5 regional tree ring δ¹⁸O chronology and land-sea thermal contrasts.
