## Abstract.

The changes in Earth's precession have an impact on tropical precipitation. These changes have been ascribed to the changes in solar radiation at the top of the atmosphere, but this cannot explain the variations in precipitation over oceans. Using energy and moisture budget equations we have shown that the surface energy fluxes, as well as vertical stability, have to be taken into consideration along with insolation, to explain these changes in precipitation. Energy fluxes explain most of the changes in precipitation, when looking at the mean response over the tropics. However, there are regions like the Arabian sea and Africa where stability change is the main cause of change in precipitation. Hence, insolation cannot be thought of as the sole driver of precipitation on orbital timescales, but surface energy and vertical stability should also be considered when looking at oceans or smaller land regions. The decrease in precipitation over the Bay of Bengal, with higher summer insolation, has been shown to be due to the decrease in surface latent heat fluxes. This is a consequence of the remote response of the atmosphere to the enhanced latent heating to the west of Bay of Bengal. This leads to a decrease in wind speed over the Bay of Bengal and hence reduces the total column energy available for convection.

## 1 Introduction

Using speleothem records, past studies have shown that the intensity of monsoon is directly proportional to insolation on orbital timescales (Wang et al., 2007, 2008; Cruz Jr et al., 2005). The model based studies suggest, however, that while this is true over land, the precipitation over tropical oceans is in general, inversely related to insolation (Clement et al., 2004; Tuenter et al., 2003; Chamales, 2014). For example, the summers of Mid-Holocene (MH), had about 20 W/m<sup>2</sup> more insolation over India, than the present day summer. An increase in summer rainfall can be found in the proxies (Ramesh, 2001; Patnaik et al., 2012; Zhang et al., 2016). The simulations of the MH monsoon by climate models indicate that the precipitation over Bay of Bengal

(BoB) was less (Hsu et al., 2010; Bosmans et al., 2012; Zhao and Harrison, 2012). The India-BoB asymmetry, is a regional manifestation of the land-ocean asymmetry in the response of precipitation to changes in the Earth's precession.

This has been explained in the previous studies using the *land-sea thermal contrast theory* of the monsoon (Zhao and Harrison, 2012; Bosmans et al., 2012). According to this theory, with increased insolation land warms more than the surrounding ocean, because of its lower thermal inertia. This increases the land-sea thermal contrast in surface temperature. However, the thermal contrast disappears after the onset of monsoon due to cooling of land by precipitation and cloud cover. In fact, good monsoon years have a lower land surface temperature (Gadgil, 2018).

The other mechanism that has been proposed is the *slow ocean response theory* (Braconnot et al., 2000; Hsu et al., 2010). The ocean, due to its higher heat capacity, takes about a month or two to respond to the insolation forcing. However, there are still many oceanic regions where, precipitation responds differently. This indicates that local processes are dominant in those regions. Thus the slow ocean response while true in general, may not explain precipitation response in small basins like the Bay of Bengal.

Some studies have used the energy balance to explain the response of precipitation to precession (Braconnot et al., 2008; Hsu et al., 2010; Merlis et al., 2013; Chamales, 2014; Battisti et al., 2014). While Braconnot et al. (2008) suggested a possible connection between changes in precipitation and changes in divergence of Moist Static Energy (MSE), Chamales (2014) and Merlis et al. (2013) have shown how they are connected using a theoretical framework. The analysis done by Merlis et al. (2013) is for the zonal mean, and this does not reflect the actual conditions in a full General Circulation Model (GCM) with continents. Hsu et al. (2010) found in their model of intermediate complexity that the changes in vertical velocity, which are in turn a response to changes in total column energy drive the changes in precipitation. This is again a tropical mean picture and regional response might be different from the tropical mean response. Also, a quantitative estimate of the parameters governing changes in precipitation is missing. Battisti et al. (2014) focused on the asymmetry between central India and Bay of Bengal, and suggested that higher summer insolation causes the near surface energy to migrate from the Bay of Bengal to India. But as shown in the appendix A, our climate model does not show such a migration in near surface energy. We propose an alternative model based on total energy in a column and stability of the column to explain the changes in precipitation in all regions of the tropics in response to changes in Earth's precession.

In this paper we have used a high-resolution, state-of-the-art fully coupled model EC-Earth in two orbital configurations, which correspond to the extremes in precession. The advantage of doing this is that, it has a similar spatial precipitation response as observed in MH, but with higher amplitude. This paper is organized as follows. The next section describes the model and the experimental setup. Section 3 outlines a simple model for the Inter Tropical Convergence Zone (ITCZ) that we have used to interpret the results. The results are described in section 4 followed by discussion and conclusions.

## 2 Model and experimental details

EC-Earth is a fully coupled ocean-atmosphere GCM, (Hazeleger et al., 2010, 2012). The model version 2.2 where, Integrated Forecasting System (IFS) is the atmospheric component was used. It has a spectral resolution of T159 (roughly  $1.125^\circ \times$

1.125°) with 62 vertical levels. The convective scheme Bechtold et al. (2008) is used along with the Balsamo et al. (2009) land surface scheme H-TESSSEL, including surface runoff. The version 2 of Nucleus for European Modeling of the Ocean (NEMO) forms the ocean component. It has a horizontal resolution of 1° with 42 vertical levels (Madec, 2008; Sterl et al., 2012). NEMO includes sea-ice model LIM2. OASIS3 coupler Valcke and Morel (2006) couples the ocean, sea-ice, land and atmosphere. EC-Earth performs well for the present day when compared to CMIP3 models in terms of climatology as well as inter-annual, spatial and temporal variability (Hazeleger et al., 2010, 2012).

Earth's precession with a period of 23,000 years, is the most dominant mode in insolation as well as in tropical precipitation. The two precession extremes, Precession minima:  $P_{\min}$  and Precession maxima:  $P_{\max}$ , correspond to summer solstice at perihelion and winter solstice at perihelion respectively (Figure 1). Table 1, shows the orbital configurations used. This causes a stronger seasonal cycle in the Northern Hemisphere (NH) and a weaker seasonal cycle in Southern Hemisphere (SH), in  $P_{\min}$  (Figure 2). The opposite occurs during a  $P_{\max}$ .

The model is run separately for each of the orbital configurations. The length of each simulation is 100 years, with the first 50 years being considered as spin-up. The last 50 years are used to generate climatology. All analysis has been done with this climatological data. The orbital parameters remain constant throughout the simulation. All other boundary conditions (e.g. the solar constant, greenhouse gas concentrations, orography, ice sheets, vegetation) were kept constant at pre-industrial levels. Vernal equinox has been fixed at 21<sup>st</sup> March, and the present day calendar is used. But since the length of season and the dates of equinoxes change along the precession cycle, the autumn equinoxes do not coincide. This is known as the *Calendar Effect*. It introduces some errors due to phasing of insolation. We do not make any corrections in order to be consistent with previous studies. For further details about the experiments see Bosmans et al. (2015).

### 3 A simple model for ITCZ

Hadley cell is a thermally direct, overturning circulation in the tropics. It takes energy away from the tropics and towards the poles. The Hadley cell has a rising branch in the deep tropics and a descending branch in the extra-tropics. This leads to moisture convergence near the rising branch. ITCZ coincides with the rising branch of the Hadley cell, and is responsible for the zone of heaviest precipitation in the tropics. Since, the Hadley cell is governed by energy and leads to moisture convergence, the characteristics of ITCZ can be described by using the conservation equations for Moist Static Energy (MSE) and moisture. Using this approach, Neelin and Held (1987) proposed a simple model for ITCZ in terms of net energy input into the atmosphere and vertical stability. This is a diagnostic model, that has been used to explain variations in rainfall due to global warming (Chou and Neelin, 2004; Chou et al., 2006) and the impact of aerosols (Chou et al., 2005). In this section we have discussed this simple model in detail.

The equations 1 and 2 correspond to the conservation of MSE and moisture in a vertical column of the atmosphere. Refer to Neelin and Held (1987) for further details on the derivation of equation 1. The time derivatives have been dropped in these equations because, the climate is assumed to be in a steady state. The angle brackets ( $\langle \rangle$ ) indicate vertical integral.

$$\langle \nabla \cdot m\mathbf{U} \rangle + \left\langle \frac{\partial m\omega}{\partial p} \right\rangle = Q_{div} \quad (1)$$

$$5 \quad \langle \nabla \cdot q\mathbf{U} \rangle + \left\langle \frac{\partial q\omega}{\partial p} \right\rangle = E - P \quad (2)$$

$$\langle A \rangle = - \int_{P_b}^{P_t} A \frac{dp}{g} \quad (3)$$

where,

P - Precipitation (mm/day)

E - Evaporation (mm/day)

10  $Q_{div}$  - Total Column Energy .i.e. the sum of all the fluxes into the atmosphere at the top and bottom of the atmosphere. (in mm/day; 1 mm/day = 26.16 W/m<sup>2</sup>). Over land, since the storage term is small, the sum of all the fluxes of energy at the surface is small. Hence,  $Q_{div}$  is mainly governed by the fluxes at the Top of Atmosphere (TOA). However, over oceans the contribution of surface fluxes is large.

q - specific humidity (Kg/Kg)

15 m – Moist Static Energy, which is the sum of internal energy, potential energy and moist energy ( $C_p T + gZ + L_v q$ )

$P_b$  – Pressure at the bottom of the atmospheric column

$P_t$  – Pressure at the top of the atmospheric column

g – acceleration due to gravity

20 Assuming  $\omega = 0$  at the top as well as the surface, leaves us with the horizontal terms only. The governing equations can be combined and simplified (equation 4).

$$P - E = \frac{Q_{div}}{GMS} \quad (4)$$

$$GMS = \frac{m_1 - m_2}{L_v(q_2 - q_1)} \quad (5)$$

$$m_1 = \frac{\int_{P_t}^{P_m} m \nabla \cdot \mathbf{U} dp/g}{\int_{P_t}^{P_m} \nabla \cdot \mathbf{U} dp/g} \quad (6)$$

$$m_2 = \frac{\int_{P_m}^{P_b} m \nabla \cdot \mathbf{U} dp/g}{\int_{P_m}^{P_b} \nabla \cdot \mathbf{U} dp/g} \quad (7)$$

where,

GMS is the Gross Moist Stability, as obtained by taking the ratio of the equations 2.11 and 2.12 from (Neelin and Held, 1987).

5  $m_1$  and  $m_2$  are respectively, the total MSE in the upper (mid-troposphere to top) and lower troposphere (surface to mid-troposphere), normalized by divergence of that layer. Thus GMS is mainly a function of vertical profiles of MSE.

$P_m$  - Pressure at mid-troposphere level

Similarly,  $q_1$  and  $q_2$  represent the total moisture in the upper and lower troposphere, normalized by divergence. The mass convergence in the lower troposphere is the same as the mass divergence in the upper troposphere. Here (Neelin and Held,

10 1987) assume that the horizontal gradients of temperature and moisture are weak within the tropics. This implies that the horizontal advection of temperature and moisture are small. This simple model attributes the changes in (P-E) to either the changes in total column energy or the vertical stability.

Figure 3 shows a scatter of (P-E) as a function of  $Q_{div}$  for the three summer months JJA taken separately. The scatter is made for Central India, BoB and North Africa for each of the precession extremes. We chose these three regions to highlight that  
 15 neglecting the role of advection, may not always be appropriate. The plot shows that the two are nearly linear, as predicted by the simple model (equation 4). The slight deviations from linearity are due to variations in GMS. As we go from  $P_{max}$  to  $P_{min}$  (low to high insolation in NH summer months), both  $Q_{div}$  and (P-E) increase over Central India and North Africa (land regions). However, both these quantities decrease over BoB (oceanic region). Being the summer months,  $Q_{div}$  is positive for all these regions.

20 To further look at the role of GMS we have shown in figure 4, a scatter of (P-E) vs GMS for the same three regions and months. There is no definite relation between the two. Based on equation 4, we would expect all positive values for GMS since, (P-E) and  $Q_{div}$  are both positive. But there are some points where GMS is negative. This indicates that the assumption about the horizontal advection terms being small is not always valid. Hence, we need to modify the definition of GMS to include horizontal advection terms.

By taking the ratio of equations 1 and 2, after multiplying equation 2 by  $L_v$  (the latent heat of vaporization for water), we get:

$$P - E = \frac{Q_{div}}{TGMS} \quad (8)$$

$$TGMS = \frac{\left\langle \nabla \cdot m\mathbf{U} + \frac{\partial m\omega}{\partial p} \right\rangle}{L_v \left\langle \nabla \cdot q\mathbf{U} + \frac{\partial q\omega}{\partial p} \right\rangle} \quad (9)$$

5 Where,

TGMS stands for Total GMS (the term “Total” indicates inclusion of all advection terms).

TGMS, has only one assumption built into it: the time derivatives of  $m$  and  $q$  are very small. This is a good assumption for a steady state climate. TGMS is particularly useful for smaller regions, where horizontal advection can be large. TGMS represents how efficiently an atmospheric column can diverge MSE per unit moisture converged into the column. This suggests that, along with the vertical profile of MSE, the amount of energy taken out of the column and the amount of moisture going into the column might be important. Since we are using climatological data, the errors in the calculations of TGMS were significant. Hence, we use the equivalence in equation 1 and 2, to estimate TGMS. Since, our goal is not to estimate the changes in (P-E), but to diagnose the cause of these changes, estimation of TGMS this way, can be justified.

## 4 Results

15 In this section we have discussed the relative importance of  $Q_{div}$  and TGMS in explaining the changes in (P-E) between  $P_{min}$  and  $P_{max}$ . First we start by giving an overview of the entire tropics and then we look at the peculiar case of the Indian subcontinent in detail.

### 4.1 Tropics

#### 4.1.1 Qualitative analysis

20 Figure 5 shows the difference in precipitation between  $P_{min}$  and  $P_{max}$ , averaged over tropical land and oceans separately. Precipitation change over tropical land is out of phase with the changes in precipitation over the oceans. Amplitude of the change is higher over land than over oceans. Also note that larger change in precipitation over land, occurs during boreal summer when compared to austral summer. This implies that the northern monsoons are more sensitive to precession than southern monsoons. Since, for both the orbital configurations Vernal equinox occurs on the same date (21<sup>st</sup> March), the difference in insolation between the two cases is very small during March. Hence, the precipitation response is also similar. Therefore the changes in land and ocean precipitation has a zero crossing during this month. Since, the quantity of interest to us is (P-E), from here onwards, all of our analysis concerns (P-E) instead of just precipitation.

In figure 6, is shown a spatial pattern of the changes in (P-E) and  $Q_{div}$  averaged over JJA (left panels) and DJF (right panels). First we discuss the response during JJA. Most of the land regions in the northern hemisphere show an increase in (P-E) and. The African monsoon is much stronger in  $P_{min}$  with an increase of about 10 mm/day. (P-E) has in general decreased over oceans. However, there are many regions over oceans where (P-E) has increased. Ocean has a much more heterogeneous response in comparison to land. This explains why the amplitude of the changes in (P-E) is small when averaged over all of the tropical oceans (figure 5).

Changes in  $Q_{div}$  having a strikingly similar spatial pattern to that of (P-E), with positive values over most of the land regions, and both positive and negative values over oceanic regions. This shows again the direct relation of (P-E) to  $Q_{div}$  as suggested by the simple model. However, there are some exceptions like the Arabian sea where,  $Q_{div}$  has decreased but (P-E) has increased. Also the region of maximum increase in (P-E) and  $Q_{div}$  are not co-located over Africa. This is on account of the changes in TGMS.

During DJF,  $P_{min}$  has lesser insolation (Figure 2) and correspondingly a decrease in (P-E) and  $Q_{div}$  is seen over land regions (Figure 6 c and d). Oceans show a heterogeneous response during DJF as well. Even though, the magnitude of changes in  $Q_{div}$  are of the same order as in JJA, the changes in (P-E) are much less in DJF as compared to JJA.

#### 4.1.2 Quantitative analysis

To quantify the relative dominance of  $Q_{div}$  and TGMS in explaining the changes in (P-E), we do the following. Writing equation 8 for  $P_{max}$ :

$$P - E = \frac{Q}{G} \quad (10)$$

where,

P, E, Q and G are precipitation, evaporation,  $Q_{div}$  and TGMS respectively. Considering  $P_{max}$  as the reference case and  $P_{min}$  as the perturbed case, we can write the following for  $P_{min}$ :

$$(P + \Delta P) - (E + \Delta E) = \frac{Q + \Delta Q}{G + \Delta G} \quad (11)$$

Where  $\Delta$  represents the perturbation from  $P_{max}$ . Now dividing by (P-E), we get

$$1 + \frac{\Delta(P - E)}{(P - E)} = \frac{1 + \Delta Q/Q}{1 + \Delta G/G} \quad (12)$$

This equation can further be modified as:

$$\underbrace{\Delta(P - E)}_{\text{Change in P-E}} = \underbrace{\frac{\frac{\Delta Q}{Q}}{1 + \frac{\Delta G}{G}}(P - E)}_{\text{Contribution from } Q_{div}} + \underbrace{\frac{-\frac{\Delta G}{G}}{1 + \frac{\Delta G}{G}}(P - E)}_{\text{Contribution from TGMS}} \quad (13)$$

Now we apply the above equation to different regions in the tropics (Figure 7). The top panel is for regions in the northern hemisphere and the bottom panel is for the southern hemisphere. The analysis was done for the summer months of the respective hemispheres (JJA for northern and DJF for the southern hemisphere). The blue stick represents the changes in (P-E), whereas the red and orange sticks are contributions from  $Q_{div}$  and TGMS.  $Q_{div}$  explains most of the changes in (P-E) over all of the land regions in northern tropics. This is however, a generalization because, TGMS contributes most to the changes in (P-E) over Africa. Because of the heterogeneous response of (P-E) over oceans, the fractional change in (P-E) is very small and the contributions from  $Q_{div}$  and TGMS are in opposite directions, thus cancelling each other out. BoB shows a decrease in (P-E) most of which is explained by changes in  $Q_{div}$  with the changes in TGMS being very small.

The southern tropics has a dominant contribution from  $Q_{div}$  over both land and oceans. However, some of the regions shown either have an equal contribution from TGMS (South Africa and Brazil) or TGMS is the dominant cause of the changes in (P-E) (North Australia and South Atlantic). Figure 7, highlights that the tropical mean response is not representative of regional responses. Hence, each region has to be studied separately to understand the physical mechanism that caused the changes in (P-E). Of particular interest is the Indian monsoon. Both BoB and Indian landmass are part of this monsoon, yet they have opposite response to precessional forcing. Hence, we discuss this asymmetric response of Indian monsoon in detail, in the following subsection.

#### 4.2 The Indian monsoon

From figure 7a, we have established that the increase and decrease of (P-E) over India and BoB respectively was due to  $Q_{div}$ . Here we examine in detail, what caused these changes in  $Q_{div}$ . We look at each of the fluxes at the surface and Top of Atmosphere (TOA) separately:

$$Q_{div} = \underbrace{LHF + SHF + Net\_Sfc\_Rad}_{\text{bottom fluxes}} + \underbrace{Net\_TOA\_LW + Net\_TOA\_SW}_{\text{TOA Fluxes}} \quad (14)$$

Where,

LHF : Surface Latent Heat Flux

SHF : Surface Sensible Heat Flux

Net\_Sfc\_Rad = Net Surface Radiation (Long wave + Short wave)

Net\_TOA\_LW : Net Top Of Atmosphere Long wave radiation

Net\_TOA\_SW : Net Top Of Atmosphere Short wave radiation

Clubbing together all the radiation fluxes into one quantity  $Q_{rad}$ , we get:

$$Q_{div} = LHF + SHF + Q_{rad} \quad (15)$$

Figure 8, is a spatial map of the differences in (P-E),  $Q_{div}$  and its components.  $Q_{div}$  has a good spatial coherence with (P-E), over most of the regions except Arabian sea. As was discussed earlier, changes in TGMS drive the changes in (P-E) over Arabian sea. Also note that (P-E) has decreased along the southern parts of the western ghats, but has increased in the northern extent of the Western Ghats.  $Q_{rad}$  bears a better resemblance to (P-E). This suggests that radiative feedbacks from clouds are present. But these feedbacks are not able to counter the large decrease in Latent Heat Flux (LHF) over Arabian sea and BoB. This makes  $Q_{div}$  decrease over these regions. In fact  $Q_{div}$  and LHF have similar spatial patterns over the oceanic regions. The changes in Sensible Heat Fluxes (SHF) are small in most places.

To establish quantitatively, what drives changes in  $Q_{div}$ , we take two regions one over Central India (15°-25°N; 73°-83°E) and the other over BoB (10°-20°N; 85°-95°E). These regions are shown as black boxes in Figure 8a. The changes in the three components of  $Q_{div}$ , over these two regions is shown in the barchart (Figure 8f). It shows the dominance of the radiative terms over India and LHF over BoB.

LHF is a function of surface wind speed, Sea Surface Temperature (SST) and how close the atmosphere is to saturation. LHF increases with increase in wind speed and SST. However, SST has increased over BoB and Southern Arabian sea by about 2°C (not shown). Hence, we look at the changes in wind speed (Figure 9). The top panel of Figure 9 (a and b) show the JJA mean winds at 850 hPa. The shading indicates wind speed and the unit vectors the direction. The axis of the Low Level Jet (LLJ) has shifted to the north and this has caused decrease in winds over BoB. Due to LLJ, deep oceanic water upwells along the coast of Somalia. This makes the SST over western parts of Arabian sea colder. However, due to the northward shift of the LLJ, the region of upwelling also shifts north, leading to cooler SSTs in the Northern Arabian sea. Thus the decrease in LHF over Arabian sea is due to weaker winds in the southern parts and colder SST in the northern parts.

Also the shift in LLJ leads to lesser moisture flux along the southern part of the Western Ghats. Hence, the decrease in (P-E). At the same time the LLJ now brings more moisture into the northern parts of Western Ghats, leading to increase in (P-E). The shift of the LLJ can be seen more clearly in Figure 9c, where the difference in winds between  $P_{min}$  and  $P_{max}$  is shown. There is a low level easterly along the equatorial Indian ocean and a low level westerly over the African landmass, also along the equator. These two low level winds converge near the eastern coast of Africa, at around longitude 40°E. Also on the same meridian is a cyclonic circulation to the north, situated over the Middle-East and an anti-cyclonic circulation to the south, over Madagascar. This resembles the Gill-like response of the atmosphere to heating of an atmospheric column (Gill, 1980).

(Gill, 1980) proposed a simple shallow water model on an equatorial  $\beta$  plane to understand the role of latent heating on surface winds. He put heat sources in different regions, to heat the entire atmospheric column over these regions. This was meant to represent convective heating due to latent heat release. When this model was forced with heating over a region at equator and another region off-equator, it produced a Kelvin wave along the equator and a Mixed Rossby-Gravity wave which had a cyclonic and an anti-cyclonic circulation in the northern hemisphere and southern hemisphere respectively. The Kelvin wave causes low level convergence along the equator, over the region of equatorial heat source. The wind response of our model, hence suggests that the wind patterns over the Indian subcontinent, are driven by atmospheric heating near equator and off-equator. Examining figure 6a, will show that the heat sources correspond to convective heating of the column due to increased precipitation over the West Equatorial Indian Ocean (WEIO) and over the Red sea. The convection over the Red sea,

is part of the African monsoon which has extended into this region. There are however, some important differences between our model and the Gill model. Ours a full GCM with non-zero mean background winds, whereas Gill model has zero mean background winds. This implies that our model response includes non-linear terms.

To summarize, the decrease in  $Q_{div}$  over BoB, is due to decreased winds over BoB. The winds decrease on account of a remote response to convective heating over WEIO and the Red Sea. The next question we want to address is, what factors lead to increased convection over these regions. To understand this, we look at the month of May, even before the Indian monsoon circulation has set up. Figure 10a and b, show the difference in  $Q_{div}$  and (P-E) for the month of May. The shading in figure 10b is for (P-E) and the unit vectors represent the changes in wind direction.  $Q_{div}$  is higher over Africa, and this causes early onset of monsoon (Figure 10b). Thus changing the low level winds along the eastern coast of Africa. This leads to reduced upwelling and increased SST. With increased SST, convection begins and this further enhances the low level convergence. This positive feedback is responsible for the convective heating over the WEIO. As the African monsoon progresses north, the region of convection over the eastern side of Africa moves over to the Red sea. This becomes the off-equatorial heat source.

## 5 Discussion and conclusions

Models with different levels of complexities: QTCM (Hsu et al., 2010), Quasi-geostrophic model EC-Bilt (Tuenter et al., 2003), GCM with slab ocean (Battisti et al., 2014) and finally the fully coupled model EC-Earth (Bosmans et al., 2018), have all shown the land-sea asymmetry in precipitation, when subjected to precessional forcing. Also the land-sea asymmetry exists irrespective of the details of the orbital configuration (Mid-holocene, or idealized experiments). This suggests that the asymmetry is on account of a very fundamental mechanism. We agree with the previous studies that this is on account of the *slow ocean response*. However, changes in precipitation over ocean are not of the same sign everywhere (Figure 6a). In fact ocean has a more heterogeneous response than land, suggesting that the role of local processes dominates over the slow ocean response in these regions. Hence, it is necessary to study smaller regions, separately to understand the precipitation response (Figure 7).

We have analysed and interpreted the response of a high resolution fully coupled model EC-Earth, to precession, by using a simple model, based on the conservations of energy and moisture. With the help of the simple model, we can diagnose the changes in precipitation, in terms of two variables .viz. the total energy going into the column ( $Q_{div}$ ) and the vertical stability of the atmosphere (GMS). We have included the horizontal advection terms which were originally assumed small (Neelin and Held, 1987). This allows us to use the simple model for relatively smaller domains, where horizontal advection terms can be large. We find that precipitation changes between precession extremes, are in general, due to changes in  $Q_{div}$ . Insolation drives changes in  $Q_{div}$  over land, whereas latent heat fluxes contribute most over oceans. Particularly, the changes in winds over the Bay of Bengal, cause latent heat fluxes to decrease. These changes in wind speed are associated with convecting heating of the atmospheric column over the west equatorial Indian ocean and the Red sea.

EC-Earth does get an increase in precipitation over the Indian landmass for minimum precession (higher summer insolation), consistent with the proxy records (Kathayat et al., 2017). However, there are no proxies for precipitation over oceanic regions.

As we move further back in time (through the Holocene), we move closer to a minimum precession configuration. This means higher summer insolation and lower winter insolation than the present day. Hence, we would expect precipitation to decrease over the Bay of Bengal as we move further back in time, through the Holocene. A speleothem chronology from the Baratang cave in the Andaman islands (Laskar et al., 2013), can be thought of as a representation of precipitation over the Bay. This chronology goes back to 4,000 years before present, and shows a long-term decreasing trend in precipitation. This suggests that the EC-Earth is doing well in capturing the land-sea asymmetry between India and Bay of Bengal.

There are however, regions where changes in stability is the main cause of changes in precipitation (eg. Africa and Arabian sea). Stability (the Gross Moist Stability) is based on the coupling between the divergence of moisture and moist static energy fluxes. This suggests that between the precession extremes, this coupling had changed. Why it changes so, requires further investigation.

## Appendix A

For orbital configuration with higher summer insolation, the rate of increase in surface temperature is high over India (due to lower thermal heat capacity). Battisti et al. (2014) suggested that this causes near surface MSE to be higher over India. It is known that the location of ITCZ coincides with that of the surface MSE (Bordoni and Schneider, 2008). Hence ITCZ migrates over India quickly and remains there. However, our plot of near surface equivalent potential temperature,  $\theta_e$  (same as near surface MSE), suggests that BoB has higher energy all throughout the year for both the precession extremes (Figure A1).

*Author contributions.* Dr. J.H.C Bosmans designed and ran the experiments. Mr. Chetankumar Jalihal, Prof. Jayaraman Srinivasan, and Prof. Arindam Chakraborty analyzed and interpreted the GCM output.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* We acknowledge support from the Centre for Excellence in the Divecha Centre for Climate Change (DCCC). This work was partially funded by DST India.

**Table 1.** The orbital configuration used for the extremes in precession, Precession minima:  $P_{\min}$ , Precession maxima:  $P_{\max}$  and the pre-industrial. ‘e’ represents eccentricity,  $\delta$  is the tilt and  $\omega$  is the longitude of perihelion. The values of these have been chosen, based on the extremes in the precession parameter  $e \sin(\pi + \omega)$ , that have occurred in the last 1 Myrs. Pre-industrial values are shown for comparison.

	e	$\delta$ (°)	$\omega$ (°)
<b>Pre-Industrial</b>	0.017	23.45	282.04
<b><math>P_{\min}</math></b>	0.056	22.08	95.96
<b><math>P_{\max}</math></b>	0.058	22.08	273.5

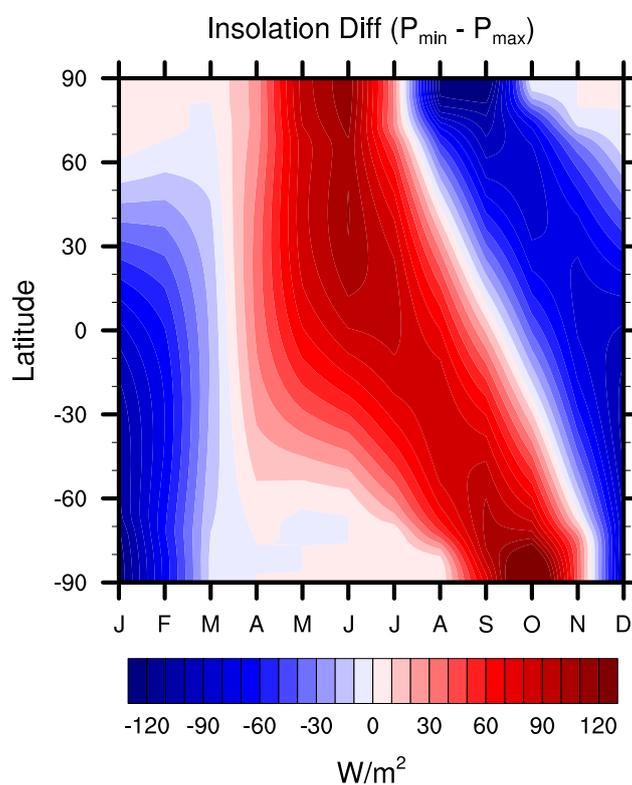

**Table 2.** This table lists all the regions used in this article, and provides there corresponding co-ordinates.

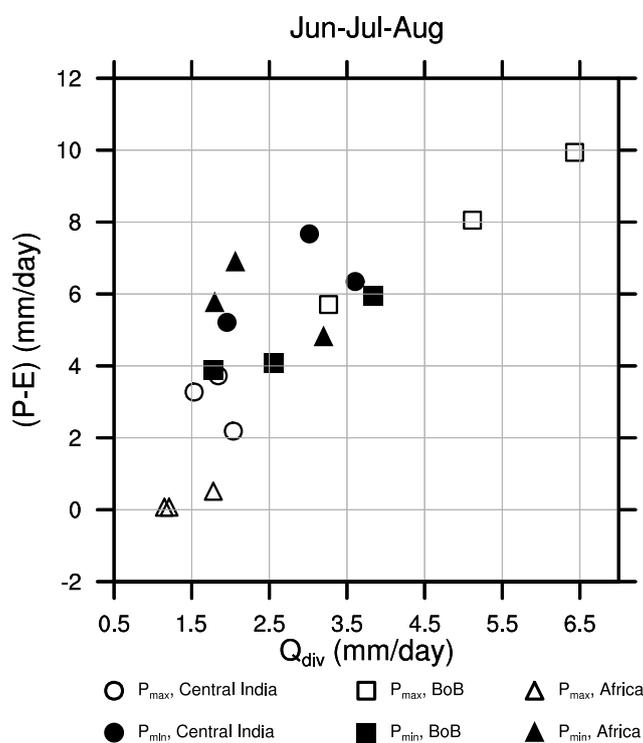

<b>Region</b>	<b>Co-ordinates</b>
<b>Northern tropics</b>	( 0°N-30°N; 0°E-360°E)
<b>Southern tropics</b>	(30°S- 0°N; 0°E-360°E)
<b>Central India</b>	(15°N-25°N; 73°E- 83°E)
<b>Bay of Bengal</b>	(10°N-20°N; 85°E- 95°E)
<b>Arabian Sea</b>	( 5°N-15°N; 60°E- 70°E)
<b>N. Africa</b>	( 5°N-15°N; 20°W- 0°E)
<b>Brazil</b>	(20°S-10°S; 70°W- 50°W)
<b>South Atlantic</b>	(20°S-10°S; 30°W- 0°E)
<b>South Africa</b>	(20°S-10°S; 15°E- 35°E)
<b>North Australia</b>	(25°S-15°S; 130°E-140°E)

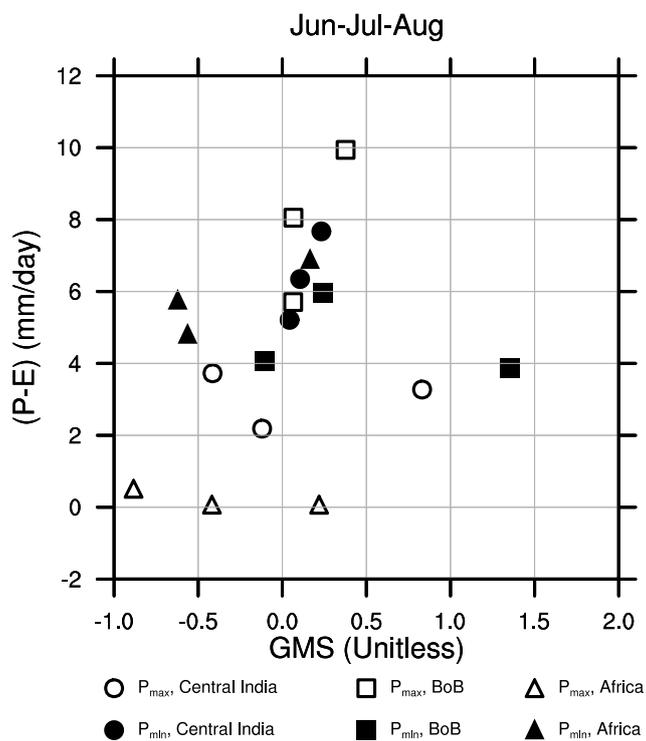

**Figure 1.** The schematic shows the orbital configuration of minimum precession ( $P_{\min}$ ) and maximum precession ( $P_{\max}$ ). In  $P_{\min}$ , summer solstice (SS) takes place at perihelion, while in  $P_{\max}$ , winter solstice (WS) coincides with the perihelion. AE and VE are the Autumn and Vernal Equinoxes respectively.

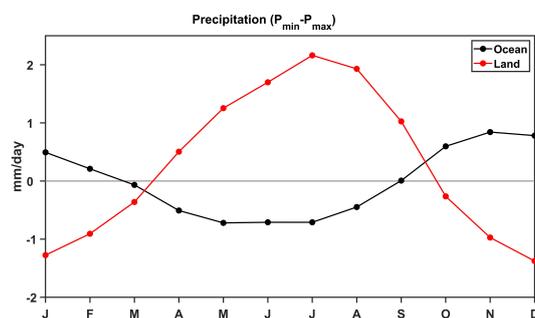

**Figure 2.** The difference in the incoming solar radiation at the top of atmosphere, between  $P_{\min}$  and  $P_{\max}$  as a function of latitude and month. This shows that insolation is higher during northern summer and lower during the northern winter in  $P_{\min}$  compared to  $P_{\max}$ .

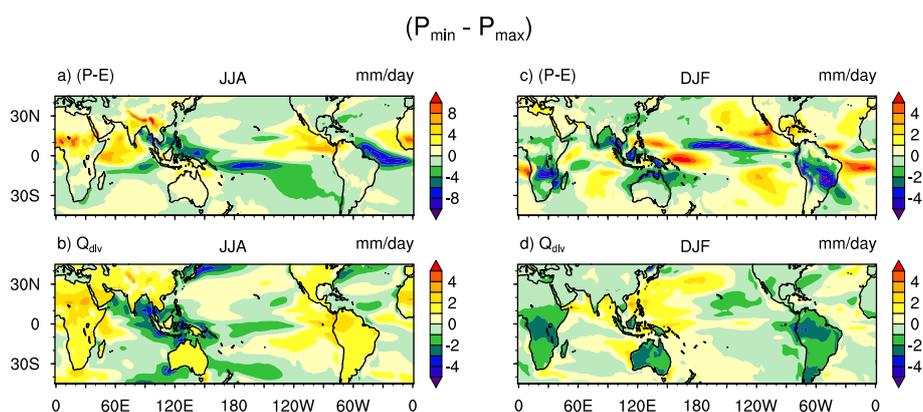

**Figure 3.** This figure shows the dependence of (P-E) on  $Q_{div}$  for three regions: Central India ( $15^{\circ}\text{N}$ - $25^{\circ}\text{N}$ ;  $73^{\circ}\text{E}$ - $83^{\circ}\text{E}$ ), Bay of Bengal ( $10^{\circ}\text{N}$ - $20^{\circ}\text{N}$ ;  $85^{\circ}\text{E}$ - $95^{\circ}\text{E}$ ) and Africa ( $5^{\circ}\text{N}$ - $15^{\circ}\text{N}$ ;  $20^{\circ}\text{W}$ - $25^{\circ}\text{E}$ ). The scatter has been made for Jun-Jul-Aug separately. The hollow and filled symbols correspond to  $P_{max}$  and  $P_{min}$  respectively. (P-E) is directly proportional to  $Q_{div}$ .

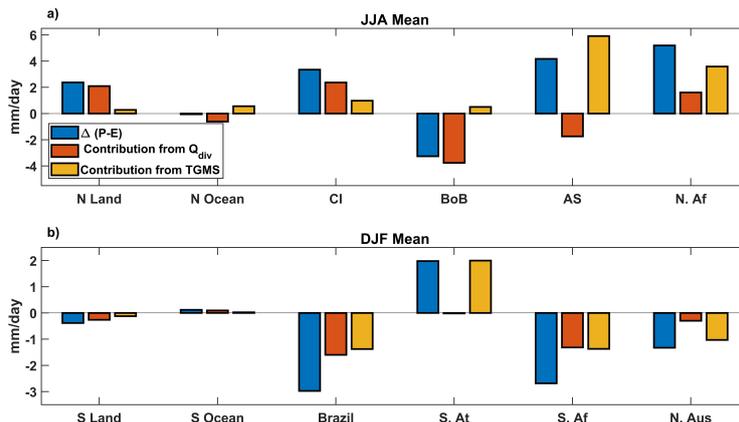

**Figure 4.** Same as figure (5), except that the x-axis is GMS. Negative values of GMS indicates that advection terms, which had been neglected, are significant.

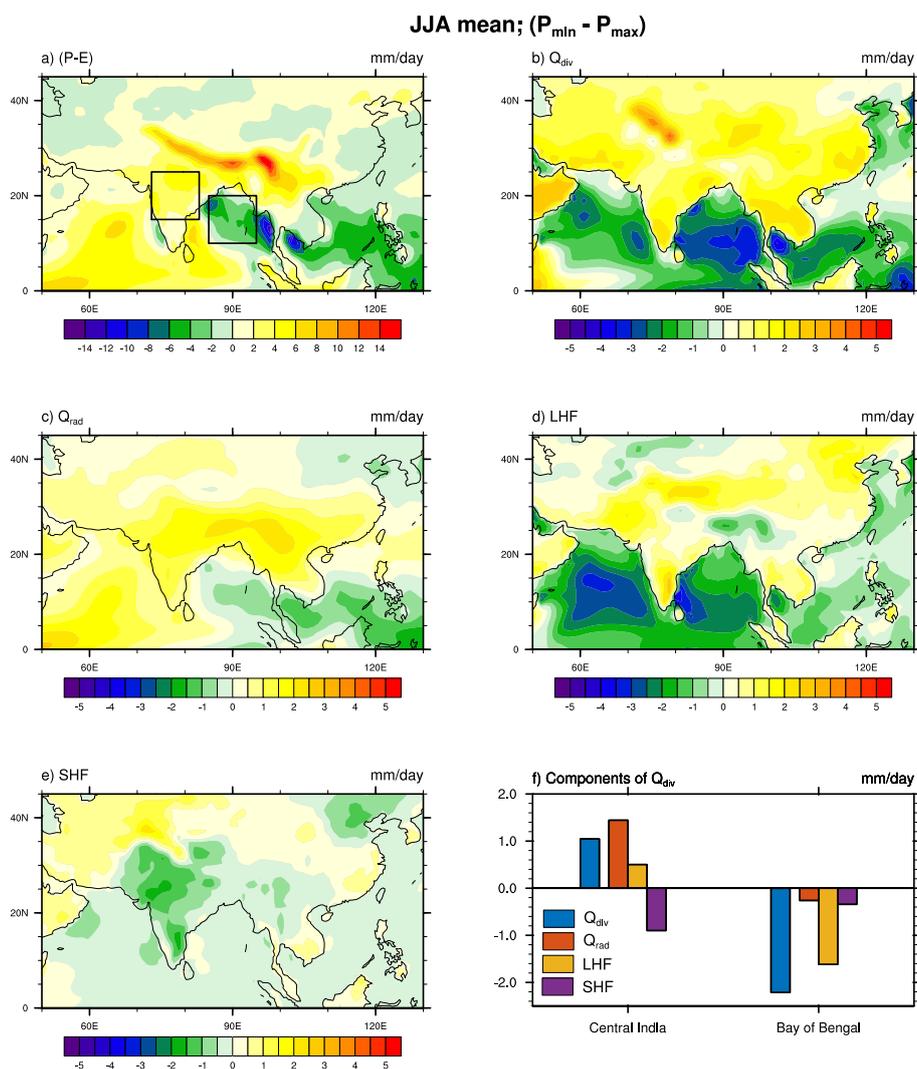

**Figure 5.** The difference in precipitation ( $P_{\min}-P_{\max}$ ) for tropical land and ocean taken separately ( $30^{\circ}\text{S} - 30^{\circ}\text{N}$ ). This shows the asymmetric response of the land and oceans to precessional forcing.

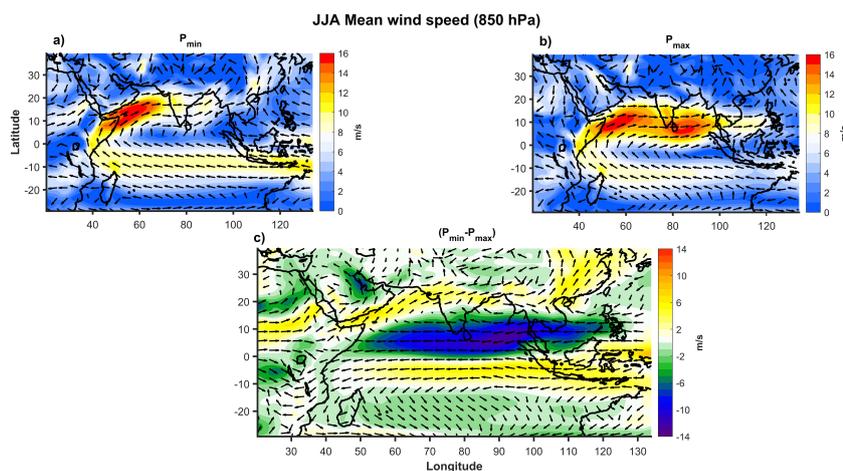

**Figure 6.** The figure shows difference in (P-E) (top panels (a) and (c)) and  $Q_{div}$  (bottom panels (b) and (d)). The left panels are for JJA and the right panels for DJF.

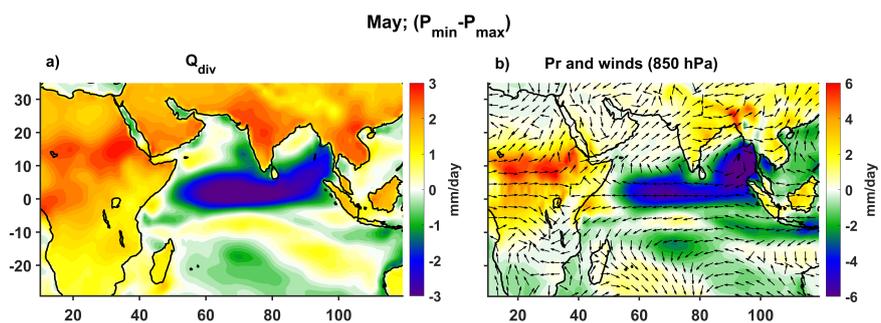

**Figure 7.** The bar chart shows the contribution of  $Q_{div}$  and TGMS to the changes in (P-E). The top panel (a) is for JJA and regions in Northern Hemisphere, while the bottom panel (b) is for regions in Southern Hemisphere and during DJF. The blue stick is the change in (P-E), while red and orange sticks represent the contribution from  $Q_{div}$  and TGMS. The abbreviations used in the top panel (a), **N Land**: Northern tropics: land only, **N Ocean**: Northern tropics: Ocean only, **CI**: Central India, **BoB**: Bay of Bengal, **AS**: Arabian sea and **N. Af**: North Africa. and in the bottom panel (b), **S Land**: Southern tropics: land only, **S Ocean**: Southern tropics: ocean only, **S. At**: South Atlantic, **S. Af**: South Africa. Refer to table 2 for the co-ordinates of these regions.

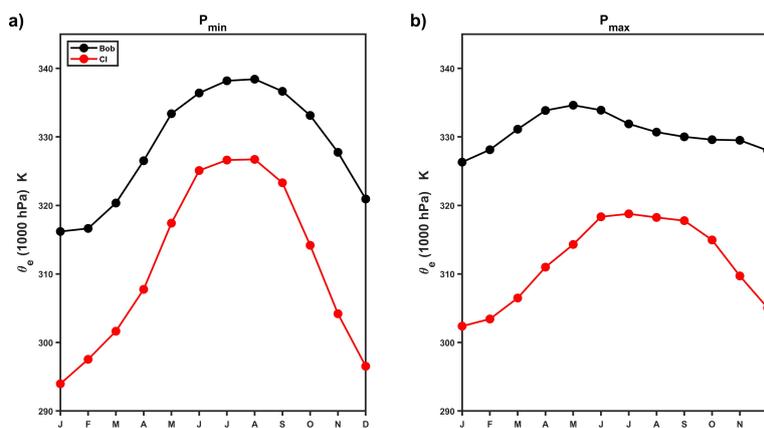

**Figure 8.** Shows the JJA mean difference ( $P_{min}-P_{max}$ ), in (a) (P-E), (b)  $Q_{div}$ , (c)  $Q_{rad}$ , (d) Latent Heat Fluxes, (e) Sensible Heat Fluxes. The two boxes shown in (a), are the regions chosen for this study: Central India (15°N-25°N; 73°E-83°E) and Bay of Bengal (10°N-20°N; 85°E-95°E). (f) shows the decomposition of  $Q_{div}$  into radiative, latent and sensible heat fluxes for the two regions. The blue bar is the change in  $Q_{div}$ , red: change in  $Q_{rad}$ , orange: change in latent heat fluxes and purple: change in sensible heat fluxes.

**Figure 9.** Top panels (a) and (a) show the JJA mean windspeed (850 hPa) in shading with unit vectors indicating direction for  $P_{min}$  and  $P_{max}$  respectively. The bottom panel (c), shows the difference in winds (850 hPa). As can be seen from (c),  $40^{\circ}$  E longitude has a convergence at equator and cyclonic circulation over the Middle-East. An anti-cyclonic circulation exists in the southern hemisphere over Madagascar. This is similar to the response of an atmosphere to equatorial plus off-equatorial heating (Gill, 1980)

**Figure 10.** The difference between  $P_{\min}$  and  $P_{\max}$  in (a),  $Q_{\text{div}}$  and (b), Precipitation along with unit vectors indicating change in wind direction, for the month of May. This shows that, the large increase in  $Q_{\text{div}}$  over Africa causes an early onset of African monsoon. Thus influencing the winds over equatorial Indian Ocean.

**Figure A1.** The plot shows the seasonal cycle of near surface equivalent potential temperature for India and BoB in the, (a)  $P_{min}$  configuration, and (b)  $P_{max}$
