**Point-by-point response to the reviews**

**Response to D. Ullman**

We thank D. Ullman for reviewing the manuscript and providing helpful comments that have improved the manuscript. Please see below for the responses to the specific comments.

**Reviewer comment 1**

Line 11 (in abstract): “These results suggest a positive feedback between continental-scale ice sheets and the Arctic temperatures that may help constrain LIS elevation...” Why is this a “positive” feedback? I tend to consider positive feedbacks to be amplifying feedbacks. But the mass-balance feedback described in this paper counteracts (or “constrains”) the initial change. LIS grows -> warmer Arctic temps -> reduced LIS surface mass balance -> LIS shrinks. Isn’t this a NEGATIVE feedback? Please consider changing throughout.

**Reply from authors**

Yes, we agree it is a bit confusing. We were thinking of this as a positive feedback in terms of temperature (higher LIS -> more heat transport -> less albedo, more water vapor -> higher temperature -> less albedo, more water vapor ...). You are right that in terms of mass balance it should be a negative feedback. To avoid all confusion, we have removed the word “positive” from the abstract.

**Reviewer comment 2**

Line 30 -> model simulations are 60 years in length; 35y for spinup, 25y for analysis. Is this enough? For the spin-up, can the authors demonstrate with some key atmospheric variables that the simulation is no longer demonstrating drift? Similarly, does 25 years provide enough time to appropriately assess a climatology?

**Reply from authors**

Model simulation lengths of 60 years is common when using a slab (mixed-layer) ocean model (the same was used in e.g. Bitz et al. 2012; Löfverström et al. 2014). Because there is no deep ocean representation in the model, the ocean spin-up is completely determined by the equilibration time-scales of mixed-layer, which is typically 20 years. The relatively short spin-up in our simulations is illustrated in Fig. 1 (enclosed in this document; see below), which shows the time evolution of the (annual) global-mean and Arctic (average north of 70N) surface temperature from the LIS0 and LIS0.25 simulations. The spin-up phase (as used in the manuscript) is highlighted with dashed lines and the climatological averaging period with solid lines. In Fig. 1, it is evident that steady state is reached after approximately 25 model years.

The reason why we chose to compute the climatology over 25 years instead of say 30 or 35 years is that we noticed that some of the simulations required a few additional years to reach equilibrium. Hence, to be on the “safe side”, we decided to compute the climatology over the last 25 years instead of the last 30 or 35 years. However, as is seen in Fig. 1b, the Arctic temperature is not very sensitive to this choice. The main result of our study, i.e. the LIS-induced Arctic warming (difference between the
LIStopo1.25 and LIStopo0 in Fig. 1b), would not change much if the averaging period was 5-10 years longer or shorter than the present choice.

Reviewer comment 3
Line 12-17 -> The surface mass balance model used in this study is a simple PDD approach. A PDD factor based on observations from modern Greenland might not be completely relevant for the LIS (see Pollard et al., 2000, Global and Planetary Change). It may be worth noting this limitation: that a fully-resolved energy balance model would provide a more complete assessment of surface mass balance. However, Pollard et al. (2000) showed that for paleo applications, conclusions of a PDD approach are generally consistent with an energy balance model. This is to say that I think the general trend of surface mass balance change due to LIS elevation (Fig. 4) is likely robust. However, the observation of positive surface mass balance over Siberia, except in the LIStopo1.25 simulation, might be sensitive to the selection of the PDD factor in the surface mass balance model. Further sensitivity analysis of the PDD factor used in these simulations may be necessary.

Reply from authors
Good idea. We have added a comment about the uncertainty of PDD models in the discussion section.

Response to Anonymous Referee 2

We thank Anonymous Referee 2 for the insightful comments on the manuscript. Please see below for the responses to the specific comments.

Reviewer comment 1
P3L29: Is the q-flux taken from Liu et al. (2009) also the one used in the PI-experiment? If not, please say so and discuss the impact of this. It shouldn’t be important for your conclusions as they follow from comparisons of the various LiStopo experiments. But the PI experiment does enter into Figs 1 and 2 and Table 1, and the interpretation thereof could be influenced by the q-flux used.

Reply from authors
Thanks for noticing this. The q-flux in the PI experiment is derived from the surface energy balance in an atmospheric model experiment with (prescribed) observed sea-surface conditions, PI insolation, and PI greenhouse gas concentrations (same as in Löfverström et al. 2014 and Liakka et al. 2016). We have clarified this in section 2 of the revised manuscript.

Reviewer comment 2
P4L4: A little more detail on the construction of the LiStopos is warranted given that they are the centerpiece of the study. In the text it sounds as if you simply multiply the actual elevation by a number, N. But is it rather the anomaly of the LGM topo wrt to PI topo that you scale with N? The fact that the N=0 case corresponds to PI topo tells me that this is rather the case. Otherwise, N=0 would mean completely flat topography.

Reply from authors
Yes, the LIS topography scaling factor (N) has been applied to the LIS topography, which is evaluated as the difference from the PI topography. Therefore, N=0 corresponds to the PI topography in North America with the albedo from the LGM LIS. We have clarified this in section 2.

Reviewer comment 3
P4L13-14: Does the qflux change also contribute to the change?

Reply from authors
Yes, potentially it does. We have highlighted that the q-flux is a potential candidate for explaining the differences between LiStopo0 and PI in section 3.1.

Reviewer comment 4
Fig 1: - Consider showing this as in a polar stereographic projection instead. Given that “Arctic” enters into the title of the paper, a highlight of Arctic changes could be in place. - Also, consider showing some standard pressure level height (say Z500) as contours on these plots, to illustrate the stationary eddy changes (if they are visible). The paper talks a lot about the changes in circulation, but nowhere are these changes visualized.
Reply from authors
This is a very good idea. We have updated the figure so that it now also includes the eddy Z500 field and is shown in polar stereographic projection.

Reviewer comment 5
P7L24: Given the importance of this analysis, spend a few sentences outlining the principle in the APRP method.

Reply from authors
We have added a sentence which briefly explains the essentials of the APRP method in section 3.3 of the manuscript.

Reviewer comment 6
P8L2: Perhaps add “(not shown)” after the discussion of changes in precipitable water.

Reply from authors
Thanks. We have added that.

Reviewer comment 7
P10L16-16: Do you perform the vertical integrals on the time-mean output from the model? This often leads to problems if the output is on (hybrid) sigma levels. Usually this has to be taken care of by performing the vertical integrals on-line on the time-step model state and then outputting time means over the vertically integrated quantities. How did you do it?

Reply from authors
The integrals were computed on pressure levels. The heat flux quantities were first interpolated from the 26 hybrid levels to 20 equally spaced pressure levels, ranging from 25 hPa to 975 hPa. In the numerical integration, each pressure level then represents the mid-point pressure of a 50 hPa thick pressure layer. The integration for each vertical column was carried out from the top of the atmosphere to the surface, which is represented by the climatological monthly-mean surface pressure. We have added some explanatory sentences about this to Appendix A.

Reviewer comment 8
P11L2-4: Could you write a little more on how you arrive at these expressions for the split-up in contributions?

Reply from authors
We arrived at those expressions from the following observations:
- The surface temperature contributions to the net outgoing LW change between two simulations is simply the difference between the outgoing LW from the surface between those simulations (Eq. B1 in the manuscript).
- The cloud contributions are estimated to be the difference between the total and clear-sky (i.e. non-cloud) LW changes (Eq. B3).
- The contributions from water vapor and lapse rate are assumed to be equal to the LW change in the clear-sky variables minus the LW change at the surface (Eq. B2).
The reason why the surface LW needs to be subtracted is to account for lapse-rate changes (determined by the difference in LW between the TOA and surface).

Note that any change in other radiative forcing agents (e.g. CO2 and aerosols) would also influence Eq. B2. However, because the LSTopo simulations use identical aerosol datasets (representative for PI) and have the same concentrations of CO2 and other greenhouse gases, only changes in water vapor and lapse rate are important for Eq. B2 in our case.

The accuracy of the individual contributions is (at least partly) validated by the fact that summing up Eqs. B1 to B3 yields the total LW change at TOA. Hence, an alternative way to understand the split-up equations is to first subtract the (relatively straight-forward) surface temperature and cloud contributions from the total LW change. The residual term then contains “everything else”, which in our case reflects changes in water vapor and lapse rate, as the other radiative forcing agents are the same in all LGM (LSTopo) experiments.

We have added some of this discussion to Appendix B.

References

List of all relevant changes

In addition to a few stylistic changes (related to language and grammar), we have made the following major changes based on the reviewers' comments (see also marked-up manuscript below):

Abstract:
- We have replaced “positive feedback” by “feedback”.

2 Model and experiments:
- We have added a sentence explaining how we calculated the q-flux to the PI experiment.
- We have clarified that the LIS topography scaling factor (N) is applied with respect to the PI topography.

3.1 Surface temperature and eddy geopotential height:
- We have added the q-flux as a potential candidate for explaining the surface temperature differences between LIStopo0 and PI.
- We have replaced Fig. 1 from a lat-lon plot of the surface temperature to a polar stereographic plot showing both the surface temperature and eddy geopotential height anomalies at 500 hPa. As a result, we also changed the title of section 3.1 and added a short paragraph (3rd in section 3.1) discussing the eddy geopotential height response in Fig. 1.

3.3 Other feedbacks
- We have added some explanatory comments on the APRP method.
- We have added “(not shown)” in the discussion about the increase in precipitable water.

4 Discussion and concluding remarks:
- We have added a comment discussing the uncertainties related to the PDD model.

Appendix A:
- We have added some sentences on how the vertical integration was performed.

Appendix B:
- We have added some sentences on how to interpret Eqs. B1 to B3.

\textbf{Abstract.} It is well known that ice sheet-climate feedbacks are essential for realistically simulating the spatio-temporal evolution of continental ice sheet over glacial-interglacial cycles. However, many of these feedbacks are dependent on the ice sheet thickness, which is poorly constrained by proxy data records. For example, height estimates of the Laurentide Ice Sheet (LIS) topography at the Last Glacial Maximum (LGM; \(\sim\)21,000 years ago) vary by more than 1 km between different ice-sheet reconstructions. In order to better constrain the LIS elevation it is therefore important to understand how the mean climate is influenced by elevation discrepancies of this magnitude. Here we use an atmospheric circulation model coupled to a slab-ocean model to analyze the LGM surface temperature response to a broad range of LIS elevations (from 0 to over 4 km). We find that raising the LIS topography induces a widespread surface warming in the Arctic region, amounting to approximately 1.5°C per km elevation increase, or about 6.5°C for the highest LIS. The warming is attributed to an increased poleward energy flux by atmospheric stationary waves, amplified by surface albedo and water vapor feedbacks, which account for about two-thirds of the total temperature response. These results suggest a strong feedback between continental-scale ice sheets and the Arctic temperatures that may help constrain LIS elevation estimates for the LGM and explain differences in ice distribution between the LGM and earlier glacial periods.

\section{Introduction}

The Last Glacial Maximum (LGM), \(\sim\)21,000 years before present (21 kyrs BP), was the apex of the last glacial period when the global ice volume reached its maximum value (Peltier and Fairbanks, 2006; Lambeck et al., 2014). In comparison with earlier glacial cycles, the LGM climate conditions are relatively well documented by proxy data records. In addition to the well-established records of Earth’s orbital configuration (Berger and Loutre, 2004), atmospheric greenhouse gas concentrations (Petit et al., 1999; Spahni et al., 2005), and sea surface temperatures (Margo Project Members et al., 2009), the LGM is the only glacial period for which the margins of the North American and Eurasian ice sheets – the Laurentide Ice Sheet (LIS) and the Fennoscandian Ice Sheet (FIS), respectively – can be reliably reconstructed from geological and geomorphological observations. These data records reveal that the LIS was by far the larger of the two, covering most of the North American
continent poleward of \(\sim 40^\circ\)N, while the FIS was comparatively small and mostly confined to northern Europe (Clark and Mix, 2002; Svendsen et al., 2004; Kleman et al., 2013). However, while the horizontal margins of the LGM ice sheets have been established, their thickness and vertical extent remain uncertain. This uncertainty is perhaps best reflected in elevation estimates of the LIS, which vary by more than 1 km between contemporary reconstructions (e.g. Peltier, 2004; Kleman et al., 2013; Abe-Ouchi et al., 2015). As a result, the Paleoclimate Modeling Intercomparison Project (PMIP4; Kageyama et al., 2017) now encourages sensitivity experiments with three distinct ice sheet reconstructions that differ in height by several hundred meters (Kageyama et al., 2017).

Modeling studies have revealed that the continental ice sheets – in particular the LIS due to its larger size and location in the westerly mean flow – had a substantial impact on the atmospheric and oceanic circulation during the last glacial cycle. For example, it has been shown that the LIS topography may have altered both the strength and orientation of the mid-latitude Atlantic jet stream (Li and Battisti, 2008; Löfverström et al., 2014, 2016; Löfverström and Lora, 2017) and the associated storm tracks and precipitation patterns (Kageyama and Valdes, 2000; Löfverström et al., 2014, 2016). Model experiments have also revealed that a higher LIS elevation helps strengthen the Atlantic Meridional Overturning Circulation (AMOC) and wind-driven North Atlantic gyre circulation, which typically results in a poleward shift of the sea-ice edge and increased temperatures in the subpolar North Atlantic (Justino et al., 2006; Eisenman et al., 2009; Pausata et al., 2011; Zhang et al., 2014; Zhu et al., 2014; Gong et al., 2015; Colleoni et al., 2016b; Klockmann et al., 2016; Gregoire et al., 2017). Moreover, several studies have shown that the LIS topography can significantly alter the atmospheric stationary wave field (i.e. the zonally asymmetric component of the time-mean atmospheric circulation; Cook and Held, 1988; Kageyama and Valdes, 2000; Roe and Lindzen, 2001; Langen and Vinther, 2008; Colleoni et al., 2016b; Liakka et al., 2016; Löfverström et al., 2014, 2016). The stationary waves can in turn influence the local temperature and precipitation anomalies that are important for the surface mass balance (Lindeman and Oerlemans, 1987; Roe and Lindzen, 2001; Herrington and Poulsen, 2011; Liakka and Nilsson, 2010; Liakka et al., 2011; Liakka, 2012; Löfverström et al., 2015; Liakka et al., 2016; Löfverström and Liakka, 2016, 2018).

Modeling studies have also shown that the LIS topography can influence the meridional (equator-to-pole) temperature profile, especially in the northern high latitudes (Justino et al., 2005; Ullman et al., 2014; Zhang et al., 2014). For example, Ullman et al. (2014) found that high-end estimates of the LGM LIS elevation increases the mean Arctic surface temperature by several degrees Celsius compared to lower reconstructions. While the authors argued that this response may be attributed to a reduced snow cover in Siberia as a result of changes in the atmospheric stationary wave field, they did not explore this narrative further. This result is however noteworthy, as it shows that the elevation of a mid-latitude topographic barrier can substantially influence the (zonal) mean climate in high latitudes. This further illuminates a gap in our current understanding of atmosphere-topography interactions and potential feedbacks between continental-scale ice sheets and the temperature in glacial climates.

Understanding the origin, physics/dynamics, and implications of such feedbacks is paramount (Fyke et al., 2018) as they can potentially help constrain the range of possible LIS elevations at the LGM, and also explain differences in the ice sheet extent between the LGM and earlier glacial periods. For example, the Penultimate Glacial Maximum (PGM; \(\sim 140\) kyrs BP) had a somewhat reversed ice-volume distribution compared to the LGM, with a larger ice sheet in Eurasia and a comparatively
smaller ice sheet in North America (Svendsen et al., 2004; Wekerle et al., 2016). There is also evidence of extensive Arctic ice shelves from the PGM; similar evidence have not been found from the LGM when the LIS was larger (Niessen et al., 2013; Colleoni et al., 2016a; Jakobsson et al., 2016; Nilsson et al., 2017).

Here we explore feedbacks between the LIS elevation and the LGM surface temperature in a comprehensive atmospheric general circulation model (AGCM) coupled to a slab-ocean model. In agreement with Ullman et al. (2014), we find that raising the LIS topography (from 0 to over 4 km) yields a widespread surface warming in the Arctic, culminating at about 6.5°C for the highest LIS. A thorough analysis of the Arctic energy budget reveals that the LIS-induced surface warming is primarily explained by an increased meridional energy-flux convergence from atmospheric stationary waves, amplified by positive feedbacks from the surface albedo and atmospheric water vapor.

The paper is organized as follows. Section 2 describes the AGCM and the experimental design and section 3 presents the results, which are further discussed in section 4.

2 Model and experiments

We use the National Center for Atmospheric Research Community (NCAR) Atmospheric Model version 3 (CAM3; Collins et al., 2006a) with T85 spectral resolution (~1.4° horizontal resolution) and 26 hybrid pressure-sigma levels in the vertical. Land processes are treated by the Community Land Model 3 (CLM3; Oleson et al., 2004). The planetary boundary conditions are prescribed as typical LGM conditions: the orbital parameters are set to appropriate values for 21 kyrs BP (Berger and Loutre, 2004), and the concentrations of CO₂, CH₄, and N₂O are prescribed as 185 ppmv (parts per million by volume), 350 ppbv (parts per billion by volume), and 200 ppbv, respectively (Petit et al., 1999; Spahni et al., 2005); CFCs are set to zero. Aerosols, vegetation, and non-glaciated land areas attain their pre-industrial (PI) configuration. We use a standard PI simulation as reference climate, which has been evaluated against observations in e.g. Löfverström et al. (2014) and Liakka et al. (2016) – the model captures the amplitude and spatial variations of the observed climate conditions (e.g. surface temperature, precipitation, and geopotential height anomalies) to a high degree.

We couple the atmospheric model to a computationally efficient slab-ocean (mixed-layer) model in order to facilitate a high number of experiments. Although the ocean representation is motionless and therefore does not account for changes in circulation, it retains the thermodynamic feedback between the ocean and the atmosphere. Sea-surface temperatures (SSTs) and sea ice are explicitly calculated from the energy balance in the ocean mixed layer (Collins et al., 2006b; Bitz et al., 2012), where the monthly oceanic heat flux convergence field (commonly referred to as the “q-flux”) and annual mixed-layer depth are derived from a 50 year LGM timeslice from the fully coupled TraCE-21ka (Transient Climate Evolution over the last 21,000 years; Liu et al., 2009; He, 2011). The PI simulation uses the q-flux and mixed-layer depth derived from an atmospheric simulation with PI boundary conditions and prescribed observed sea-surface conditions (see also Löfverström et al., 2014; Liakka et al., 2016). All simulations are integrated for 60 years, of which the first 35 model years are regarded as spin-up, and the remaining 25 years are averaged to create the atmospheric climatological fields used in the analysis.
The ice sheets in North America and Eurasia are derived from the LGM reconstruction in Kleman et al. (2013), which is broadly similar to other contemporary reconstructions (cf. black dashed contours in Fig. 1 with Peltier, 2004; Abe-Ouchi et al., 2015); the maximum LIS elevation is approximately 3.3 km.

We conduct a total of six steady-state simulations with different heights of the LIS. In each simulation the LIS height (evaluated with respect to the PI topography) is multiplied by a uniform constant \( N \), which takes on values between 0 and 1.25 in increments of 0.25. The LIS morphology and spatial extent therefore remains the same in all experiments, but the elevation is altered: \( N = 0 \) represents present-day North American orography and LGM land albedo (glacial mask), \( N = 1 \) is the "standard" LGM case with unscaled LIS topography (\( \sim 3.3 \) km maximum elevation; Kleman et al., 2013), and \( N = 1.25 \) has a maximum LIS elevation of \( \sim 4.1 \) km, approximately similar to the ICE-5G reconstruction (Peltier, 2004). The LGM sensitivity experiments are referred to as LIStopo\( N \), where \( N \) is the topography scaling factor. As the objective of this study is to evaluate the importance of the LIS topography on the surface temperature, the height of the FIS remains constant (Kleman et al., 2013) in all experiments.

3 Results

3.1 Surface temperature and eddy geopotential height

Figure 1a,b shows the annual-mean surface temperature from the PI and LIStopo0 simulations. The LIStopo0 surface temperature is substantially colder than PI, particularly in high latitudes. This cooling is explained by the high surface albedo from the ice sheets, a more extensive sea ice cover, lower concentrations of atmospheric greenhouse gases, differences in insolation, and ocean-circulation parameterization (q-flux).

The annual-mean surface temperature response to the LIS topography is shown in Fig. 1c-g. This is evaluated as the difference in surface temperature with respect to the LIStopo0 simulation. The largest cooling is confined to the LIS area (as a result of the surface elevation change), and some smaller cold anomalies are found in the mid and subpolar North Atlantic. The cooling east of the LIS topography is a typical downstream response to topographically-induced stationary waves as cold air is advected from the ice sheet interior by the westerly mean flow (e.g. Roe and Lindzen, 2001; Liakka et al., 2011). Elsewhere, raising the LIS topography results in warmer temperatures, particularly in non-glaciated high-latitude land areas and in the Arctic basin (Fig. 1c-g).

The spatial variability of the topographically-forced temperature response correlates reasonably well with changes in the stationary wave field (shown here by the 500 hPa eddy geopotential height; gray contours in Fig. 1c-g): the slight cooling in the subpolar North Atlantic is typically associated with a stationary trough, while the warming in Alaska and eastern Siberia coincides with a ridge (Fig. 1c-g).

In contrast to the eddy geopotential height field (which by definition cancels in the zonal mean), the zonal-mean temperature response to the LIS topography is significantly different from zero, particularly at high latitudes. The annual-mean surface temperature in the Arctic increases by approximately 1.5°C per km of LIS elevation (Fig. 2). The high-latitude warming is present in all seasons (Fig. 2), but is strongest in boreal winter (December-January-February; DJF). The seasonal persistence
of the Arctic warming suggests that it is driven by changes in both atmospheric dynamics and physics. While the effects of
dynamics are typically more pronounced in winter, many radiative features (such as the surface albedo-temperature feedback)
are more important in summer when the insolation is higher (note that insolation in boreal winter is negligible at these latitudes).

3.2 Role of atmospheric dynamics

Motivated by the apparent connection between the LIS height and Arctic temperatures, the following sections analyze how the
atmospheric meridional heat flux changes with a height of the LIS topography.

3.2.1 Basic theory

In steady-state, changes in the atmospheric energy storage is zero for annual climatologies (Peixoto and Oort, 1992; Trenberth
et al., 2001; Serreze et al., 2007), implying that the atmospheric energy balance can be written as (e.g. Serreze et al., 2007):

\[ C = S - R, \] (1)

where \( C \equiv -\nabla \cdot \mathbf{F} \) is the convergence of vertically-integrated (annual mean) horizontal energy flux, \( R \) the net radiation at the
top-of-the-atmosphere (TOA), and \( S \) the energy balance at the surface (\( R \) and \( S \) are both positive downward). The surface
energy balance is defined as the sum of the net radiation and turbulent fluxes. Similarly, the latent energy-flux convergence
\( (C_L \equiv -\nabla \cdot \mathbf{F}_L) \) is proportional to the difference between precipitation \( (P) \) and evaporation \( (E) \):

\[ C_L = L_v(P - E), \] (2)

with the latent heat of evaporation \( L_v = 2.5 \times 10^6 \) J kg\(^{-1}\). The dry-static energy-flux convergence \( (C_{DS}) \) is defined as the
residual of the total and latent energy fluxes\(^1\) \( (C - C_L) \), i.e.:

\[ C_{DS} = S - R - L_v(P - E). \] (3)

The implied (zonally and vertically integrated) northward energy flux at each latitude is obtained by integrating Eq. 1:

\[ F(\phi) = -a^2 \int_0^{\phi} \int_{-\pi/2}^{\phi} C(\phi', \lambda') \cos(\phi')d\phi'd\lambda', \] (4)

where \( a \) is Earth’s radius, \( \lambda \) is the longitude, and \( \phi \) the latitude (both defined in radians). The equivalent northward fluxes of
latent \( (F_L) \) and dry-static \( (F_{DS}) \) energy are obtained by substituting \( C \) with \( C_L \) and \( C_{DS} \) in Eq. 4.

The energy flux quantities can be further decomposed into the relative contributions from the zonal-mean circulation, sta-
tionary eddies, and transient eddies by using atmospheric state variables at model levels; see Peixoto and Oort (1992) and

\(^1\) The kinetic energy is neglected as it is much smaller (typically two orders of magnitude) than the dry-static and latent energy contributions.
3.2.2 Meridional flux of atmospheric energy

Figure 3a-c shows the implied atmospheric northward energy fluxes \( F, F_L, \) and \( F_{DS} \) from our simulations. There is a slight increase of total energy flux \( F \) in the LGM simulations with respect to PI, and the Northern Hemisphere (NH) peak value is shifted slightly equatorward (Fig. 3a). The LGM change in energy flux is largely represented by a comparable shift in dry static energy \( F_{DS} \) (Fig. 3c), while the latent energy flux \( F_L \) shows an overall reduction in the NH mid-latitudes (Fig. 3b).

The increase of total energy transport at the LGM (with respect to PI) is in agreement with previous results from both coupled atmosphere-ocean models, and from atmosphere models forced by prescribed sea-surface conditions (Hall et al., 1996; Hewitt et al., 2003; Shin et al., 2003; Li and Battisti, 2008; Murakami et al., 2008). Similarly, the increase (decrease) of dry-static (latent) energy flux is a typical LGM response in fully-coupled models (Li and Battisti, 2008; Murakami et al., 2008) and is partially explained by a weaker hydrological cycle in colder climates (Alexeev et al., 2005; Held and Soden, 2006).

To investigate the role of the LIS topography in more detail, we analyze how different atmospheric circulation regimes influence the meridional energy flux. Figure 3d-f shows how the meridional flux of dry-static energy is influenced by the time- and zonal-mean atmospheric circulation \( F_{DSM} \), stationary eddies \( F_{DSS} \), and transient eddies \( F_{DST} \) (see Appendix A for details).

The majority of the increase in low-latitude dry-static energy flux is attributed to changes in the mean circulation (Fig. 3d). These changes are however not directly attributed to the LIS topography, as all LGM simulations show a similar response. The LIS topography is found to be more important for the meridional flux of dry-static energy from stationary \( F_{DSS} \) and transient eddies \( F_{DST} \). In LIStopo0, \( F_{DSS} \) is roughly similar to the PI, whereas the peak \( F_{DST} \) is somewhat higher and shifted equatorward (Fig. 3e,f). Raising the LIS elevation yields a gradual increase (decrease) of stationary (transient) dry-static energy flux in the NH extratropics (Fig. 3e,f), in broad agreement with the fully coupled simulations in Li and Battisti (2008) and Murakami et al. (2008). Here we demonstrate that these changes can be primarily attributed to the LIS topography, as all other boundary conditions remain unchanged in our LGM sensitivity simulations.

3.2.3 Energy-flux convergence in the Arctic

While the meridional energy flux (as calculated by Eq. 4) is valuable for identifying structural changes of the large-scale atmospheric circulation, it reveals limited information on how the mean climate responds. For that purpose, the energy-flux convergence (meridional derivative) is a more useful metric than the flux itself (see Eq. 1).

Table 1 shows the horizontal atmospheric energy-flux convergence in the Arctic polar cap (area-weighted average of all grid points poleward of 70°N). The energy-flux convergence in the PI simulation amounts to 102 W m\(^{-2}\), which is in close agreement with estimates from atmospheric reanalysis data (100 to 103 W m\(^{-2}\); Serreze et al., 2007). The total energy-flux convergence \( C \) in LIStopo0 is reduced by 6 W m\(^{-2}\) compared to the PI, which is primarily explained by a decrease in the latent energy-flux convergence \( C_L \) (Table 1). Raising the LIS topography yields a gradual increase of the total energy-flux convergence \( C \) by an average rate of \( \sim 1.5 \) W m\(^{-2}\) km\(^{-1}\), resulting in similar values to PI for the highest LIS. This increase stems from an enhanced contribution from the dry-static energy-flux convergence \( C_{DS} \), in particular from stationary waves.
the latent energy-flux convergence ($C_L$) is approximately the same in all LGM simulations. For the highest LIS, the stationary-wave contribution to the total Arctic energy-flux convergence even dominates over the contribution from transient eddies ($C_{DST}$; Table 1). The reduction in transient eddy activity is characteristic for a reduced storminess at the LGM; see Li and Battisti (2008), Donohoe and Battisti (2009) and Rivière et al. (2018) for further discussions on this topic.

### 3.3 Other feedbacks

The results in Fig. 3 and Table 1 demonstrate that the LIS topography has a dominant influence on the LGM stationary-wave field (in agreement with Cook and Held, 1988; Kageyama and Valdes, 2000; Löfverström et al., 2014). Although the increased energy-flux convergence from the LIS-induced stationary waves is largely compensated by a comparable reduction from transient eddies, the net effect is a positive contribution (warming) to the Arctic energy balance ($\delta C$ in Table 1). All else being equal, we can crudely estimate the influence of the LIS-induced atmospheric circulation on the Arctic temperature by assuming a typical value of the surface temperature (Planck) feedback parameter ($\lambda_T = 3.2 \text{ W m}^{-2} \text{ K}^{-1}$; Flato et al., 2013). For the highest LIS, the contribution from the atmospheric circulation is roughly $\delta C/\lambda_T \approx 2^\circ\text{C}$, which is significantly lower than the $\sim 6.5^\circ\text{C}$ seen in Fig. 2. This difference suggests that other (positive) feedbacks are important for the LIS-induced warming as well.

As seen in Eq. 1, changes in the total energy-flux convergence ($C$) reflect an imbalance between the energy fluxes at the surface ($S$) and at the top of the atmosphere ($R$). For a climate in balance, $S$ is close to zero over land and represented by the horizontal heat flux divergence in the ocean (i.e. $S = -C_{\text{ocean}}$; Trenberth et al., 2001; Serreze et al., 2007). As we use a slab-ocean model, the representation of the ocean heat flux is identical in our simulations, implying that the surface energy balance ($S$) over the ocean remains unchanged when changing the LIS elevation. Any LIS-induced change in the atmospheric energy-flux convergence should therefore be compensated by an equivalent change in the TOA net radiation balance:

$$\delta C + \delta R = 0.$$  \hspace{1cm} (5)

The influence of the LIS elevation on the Arctic TOA net radiation is shown in the left-most column of Table 2. As suggested in Eq. 5, these values have a similar magnitude as the atmospheric energy-flux convergence ($\delta C$ in Table 1). The relatively small differences stem from the fact that the (annual-mean) Arctic surface energy balance is not completely identical in all simulations, but varies between 9.1$\pm$0.2 W m$^{-2}$ as a result of slow processes in the land model. These small inconsistencies are however not important for the interpretation of our results and conclusions.

To evaluate the contributions from individual feedbacks to the LIS-induced Arctic warming, the TOA net radiation change ($\delta R$) is separated into radiative contributions from changes in surface albedo ($\delta R_a$), water vapor and lapse rate ($\delta R_{wv+l_r}$), total cloudiness ($\delta R_{cld}$), and surface temperature (i.e. the Planck feedback: $\delta R_T$). The estimated strengths of these feedbacks are obtained by separately calculating the contributions to the shortwave (SW) and longwave (LW) parts of the radiative spectrum. The SW decomposition is carried out using the Approximative Partial Radiative Perturbation (APRP) method, which uses a simplified model to separate changes in net incoming SW radiation into contributions from surface albedo, clouds, non-cloud (clear-sky) SW, and a residual term (Taylor et al., 2007); the LW decomposition is provided in Appendix B. While the
surface albedo ($\delta R_\alpha$) and Planck ($\delta R_T$) feedbacks, respectively, influence the SW and LW radiation separately, the other terms ($\delta R_{wv+lr}$ and $\delta R_{cld}$) are assumed to contribute to both (see Appendix B). Note that the residual term from the APRP method is omitted here as it is not relevant for the discussion. This term is also comparably small so that the total TOA radiation change is approximately equal to the sum of all individual feedbacks, i.e.:

$$\delta C + \delta R_\alpha + \delta R_{wv+lr} + \delta R_{cld} + \delta R_T \approx 0. \quad (6)$$

The radiative contribution from each feedback is shown in Table 2. It is evident that the surface albedo ($\delta R_\alpha$) and water vapor ($\delta R_{wv+lr}$) are the most important feedbacks (contributing to increase the Arctic temperature) when raising the LIS elevation; cloud feedbacks ($\delta R_{cld}$) are virtually negligible. For the highest LIS elevations, the combined influence of changes in surface albedo and water vapor yield a positive radiative contribution of about 14 W m$^{-2}$, thus exceeding the contribution from the energy-flux convergence ($\delta C$ in Table 1) by approximately a factor 2. Of these two feedbacks, the water vapor feedback is overall about twice as large as the surface albedo feedback, mediated by a $\sim 30\%$ increase of the total precipitable water content between LISTopo0 and LISTopo1.25 (not shown). To compensate for the warming contributions from the atmospheric energy-flux convergence, and the water vapor and albedo feedbacks, there is an increased outgoing LW radiation from the surface as a result of higher temperatures (Planck feedback; $\delta R_T$), amounting to about 21 W m$^{-2}$ for the highest LIS reconstruction (Table 2).

4 Discussion and concluding remarks

Here we investigate how the LIS topography influences the Arctic surface temperature, using a comprehensive AGCM coupled to a slab-ocean model. Our results show that increasing the LIS elevation (from 0 to over 4 km), while keeping all other boundary conditions fixed at their LGM configuration, results in an annual-mean Arctic warming in excess of 6.5°C. This warming is primarily attributed to a net increase in the atmospheric energy-flux convergence in high latitudes, which is further reinforced by positive feedbacks from a reduced surface albedo and a higher atmospheric water vapor content.

The correlation between Arctic temperatures and the LIS elevation suggests that LGM LIS may have helped reduce the equator-to-pole temperature gradient. This is also supported by annual-mean surface mass balance (SMB) estimates (Fig. 4), evaluated as the difference between accumulation (precipitation) and ablation using the Positive-Degree-Day (PDD) approach (Braithwaite and Olesen, 1989; Reeh, 1991) from the ice-sheet model SICOPOLIS (Greve, 1997; Calov and Greve, 2005). Figure 4 shows that most (non-glaciated) Arctic land areas change from a positive to negative a SMB when raising the LIS elevation, suggesting that the presence of the LIS topography may have helped keeping Alaska and Siberia largely ice free at the LGM (in agreement with Roe and Lindzen, 2001; Liakka et al., 2016; Löfverström and Liakka, 2016). Furthermore, areas with positive SMB are found in Siberia in all simulations except LISTopo1.25, which suggests that the maximum LIS elevation at the LGM may have been higher than our default LIS reconstruction (LISTopo1; 3.3 km). It is important to stress that this result likely is model dependent (e.g. the global-mean surface temperature at the LGM is found to be between 3.1°C and 5.8°C cooler than preindustrial in the PMIP2 models; Braconnot et al., 2007). In addition, the ablation calculations presented here
should only be considered a crude first-order estimate, as the PDD model relies on the assumption that the annual melt-potential is a function of the monthly-mean surface temperature. It is therefore important to assess the impact of LIS elevation on the SMB using more realistic ablation representations in other models (e.g. SMB parameterisations that are based on the surface energy balance) before we can use this information to constrain the range of possible LIS elevations. With the result presented here, however, we hope to encourage such experiments in the future.

The feedback between continental-scale ice sheets and meridional temperature distribution presented here may also provide a better understanding of glacial environments beyond the LGM. For example, Jakobsson et al. (2016) showed evidence of a thick and partially grounded Arctic ice shelf during the penultimate glacial maximum (PGM), when the LIS is believed to have been considerably smaller than its LGM size (Dyke et al., 2002; Colleoni et al., 2016b; Wekerle et al., 2016). Here we obtain positive SMB across most of the Arctic coastal areas for the lowest LIS topographies ($N \leq 0.5$), while higher LIS elevations yield negative SMB in these areas (Fig. 4). Hence, these results suggest that the smaller LIS size at the PGM may have been a contributing factor to the formation of an extensive Arctic ice shelf.

The main limitation of this study is that we use a slab-ocean model and thus neglect potential changes in the ocean circulation. However, these changes are not expected to influence the first order conclusions from this study. There are two main reasons for this. First (i), the primary source of the Arctic warming found here, i.e. the increased energy flux by stationary waves, is also featured in many LGM experiments with fully-coupled models (e.g. Li and Battisti, 2008; Murakami et al., 2008). Second (ii), the direct impact of the ocean circulation on the Arctic temperature is only important in regions that were mostly free of sea-ice at the LGM. Proxy data from the LGM show that essentially only the subpolar North Atlantic sector, a region strongly influenced by AMOC variability, was characterized by seasonally ice-free conditions poleward of $70^\circ$N (Margo Project Members et al., 2009). However, there is strong evidence from several fully-coupled models that raising the LIS elevation yields a stronger AMOC (Justino et al., 2006; Eisenman et al., 2009; Pausata et al., 2011; Ullman et al., 2014; Zhang et al., 2014; Zhu et al., 2014; Gong et al., 2015; Klockmann et al., 2016; Gregoire et al., 2017), which is expected to amplify the Arctic warming signal.

Put in perspective, the LIS-induced Arctic energy-flux convergence found here ($\sim 6.5 \text{ W m}^{-2}$) even exceeds the radiative forcing from a doubling of atmospheric CO$_2$ ($\sim 4 \text{ W m}^{-2}$; e.g. Hansen et al., 1997), emphasizing the importance of the LIS topography for the LGM climate. A similar influence on the stationary waves has not been found for the FIS or the smaller (pre- and post-LGM) configurations of LIS (e.g. Eisenman et al., 2009; Liakka et al., 2016; Gregoire et al., 2017). Hence, it is possible that the stationary-wave induced energy flux, and thus also the associated temperature feedback, is only important when the continental ice sheets are sufficiently large to interact with the westerly mean flow (some evidence of this is shown in Lofverstrom et al., 2014; Lofverstrom and Lora, 2017). To explore the limits of this feedback with respect to different ice-sheet configurations and atmospheric mean states is beyond the scope of this study, but we hope that results from the PMIP4 experiments (Kageyama et al., 2017) – in particular the sensitivity experiments with different ice-sheet reconstructions – will help illuminate some of these issues.
Data availability. The model output files can be obtained from the first author (johan.liakka@nersc.no) upon request.

Appendix A: Contributions from the circulation to the meridional energy flux

Here we estimate the (zonally and vertically integrated) northward energy flux from the time- and zonal-mean circulation, as well as stationary and transient eddies. We refer to Peixoto and Oort (1992) for a more comprehensive review of this topic. The total meridional energy flux (Eq. 4) can be expressed in atmospheric state variables as:

\[
F(\phi) = 2\pi a \cos(\phi) \int_{0}^{p_s} \left[ \overline{v h_{DS}} + \overline{v h_L} \right] \frac{dp}{g},
\]  

where \(p\) is the pressure, \(p_s\) the surface pressure, \(v\) the meridional wind and \(g = 9.8 \text{ m s}^{-2}\) the gravitational acceleration. Here, \(h_{DS} \equiv c_p T + g z\) represents the dry-static energy (per unit mass), defined as the sum of the internal and potential energy, where \(T\) is the temperature, \(c_p = 1004 \text{ J kg}^{-1} \text{ K}^{-1}\) the specific heat capacity, and \(z\) the geopotential height. The latent energy is given by \(h_L \equiv L v q\), where \(q\) is the specific humidity, and \(L_v = 2.5 \times 10^6 \text{ J kg}^{-1}\) is the latent heat of evaporation. Overbars denote time mean and square brackets zonal mean. The dry-static energy flux can be separated into the relative contributions from different components of the atmospheric circulation as:

\[
\overline{v h_{DS}} = \overline{v} \overline{h_{DS}} + \overline{v^* h_{DS}^*} + \overline{v' h_{DS}'};
\]  

where the terms on the right-hand side represent the zonal-mean circulation, stationary eddies and transient eddies, respectively; asterisks and primes represent deviations from the zonal and time mean states. The equivalent contributions from each circulation regime to the dry-static energy flux is given by:

\[
F_{DSM} = 2\pi a \cos(\phi) \int_{0}^{p_s} \overline{v} \overline{h_{DS}} \frac{dp}{g},
\]

\[
F_{DSS} = 2\pi a \cos(\phi) \int_{0}^{p_s} \overline{v^* h_{DS}^*} \frac{dp}{g},
\]

\[
F_{DST} = F_{DS} - F_{DSM} - F_{DSS}.
\]

Hence, the contribution from transient eddies is determined as the residual of the total, zonal mean, and stationary components of the circulation. The equivalent latent energy flux can be obtained from Eqs. A2 to A5 by substituting \(h_{DS}\) with \(h_L\).
The corresponding horizontal energy-flux convergence is calculated by differentiating Eqs. A3 to A5 with respect to the latitude \( \phi \), and dividing by \(-2\pi a^2 \cos(\phi)\), i.e.:

\[
C_{DSM} \equiv -\frac{1}{2\pi a^2 \cos(\phi)} \frac{\partial F_{DSM}}{\partial \phi} = -a^{-1} \int_0^{p_*} \frac{\partial}{\partial \phi} \left[ \frac{[\nabla][h_{DS}]}{g} \right] dp,
\]

(A6)

\[
C_{DSS} \equiv -\frac{1}{2\pi a^2 \cos(\phi)} \frac{\partial F_{DSS}}{\partial \phi} = -a^{-1} \int_0^{p_*} \frac{\partial}{\partial \phi} \left[ u^* h_{DS}^* \right] dp,
\]

(A7)

\[
C_{DST} = C_{DS} - C_{DSM} - C_{DST},
\]

(A8)

where \( C_{DS} \) is defined in Eq. 3. To calculate the integrals in Eqs. A6 and A7, the heat flux quantities are first interpolated from the model’s 26 hybrid sigma-pressure levels to 20 equally thick pressure layers (layer mid-points range from 25 to 975 hPa), followed by a numerical integration from the top layer to the surface pressure.

Appendix B: Disentangling longwave feedbacks on the TOA net radiation balance

To estimate the TOA longwave (LW) contributions from changes in the surface temperature \( \delta R_{LW}^{T} \), water vapor and lapse rate \( \delta R_{wv+lr}^{LW} \), and clouds \( \delta R_{cld}^{LW} \) between two simulations (subscripts 1 and 0), we use the following equations (positive flux downward):

\[
\delta R_{LW}^{T} = R_{LW}^{s,1} - R_{LW}^{s,0}, \tag{B1}
\]

\[
\delta R_{wv+lr}^{LW} = (R_{c,1}^{LW} - R_{s,1}^{LW}) - (R_{c,0}^{LW} - R_{s,0}^{LW}), \tag{B2}
\]

\[
\delta R_{cld}^{LW} = (R_{1}^{LW} - R_{c,1}^{LW}) - (R_{0}^{LW} - R_{c,0}^{LW}). \tag{B3}
\]

The subscripts “s” and “c” represent surface and clear-sky fluxes, respectively. The clear-sky and total fluxes are taken directly from the model output, and the surface fluxes are computed from the surface temperature using Stefan Boltzmann’s law for black body radiation (surface flux proportional to the fourth power of temperature).

An important property of Eqs. B1 to B3 is that the individual contributions add up to total LW change: \( \delta R_{LW}^{T} = \delta R_{T}^{LW} + \delta R_{wv+lr}^{LW} + \delta R_{cld}^{LW} \). Hence, an alternative way to interpret the individual contributions presented here is to first subtract the surface temperature and clouds contributions from the total LW change. The residual term then contains all other LW contributions, including aerosols, greenhouse gases, water vapor and lapse rate. However, because the aerosol and greenhouse gas concentrations are identical in the LGM simulations, this term only reflects changes in water vapor and lapse rate.
Finally, the combined SW and LW contributions to the TOA net radiation changes are evaluated as:

\[ \delta R = \delta R^{SW} + \delta R^{LW}, \]  
\[ \delta R_\alpha = \delta R^{SW}_\alpha, \]  
\[ \delta R_{wv + lr} = \delta R^{SW}_{wv + lr}, \]  
\[ \delta R_{cld} = \delta R^{SW}_{cld} + \delta R^{LW}_{cld}, \]  
\[ \delta R_T = \delta R^{LW}_T, \]

where \( \delta R^{SW} \) is the total TOA SW change, and the quantities \( \delta R^{SW}_\alpha \), \( \delta R^{SW}_{cld} \) and \( \delta R^{SW}_{wv + lr} \) represent the TOA SW contributions from the surface albedo, clear-sky atmosphere (mainly due to changes in the SW absorption by water vapor) and clouds derived from the APRP method (Taylor et al., 2007).
