Abstract. The oxygen and hydrogen isotopic compositions of water in fluid inclusions in speleothems are important hydroclimate proxies because they provide information on the isotopic compositions of rainwater in the past. Moreover, because isotopic differences between fluid inclusion water and the host calcite provide information on the past isotopic fractionation factor, they are also useful for quantitative estimation of past temperature changes. The oxygen isotope ratio of inclusion water ($\delta^{18}\text{O}_{\text{fi}}$), however, may be affected by isotopic exchange between the water and the host carbonate. Thus, it is necessary to estimate the bias caused by this post-depositional effect for precise reconstruction of palaeo-temperatures. Here, we evaluate the isotopic exchange reaction between inclusion water and host calcite based on a laboratory experiment involving a natural stalagmite. Multiple stalagmite samples cut from the same depth interval were heated at 105°C in the laboratory for 0–80 hours. Then, the isotopic compositions of the inclusion water were measured. In the 105°C heating experiments, the $\delta^{18}\text{O}_{\text{fi}}$ values increased from the initial value by 0.7‰ and then remained stable after ca. 20 hours. The hydrogen isotope ratio of water showed no trend in response to the heating experiments, suggesting that the hydrogen isotopic composition of fluid inclusion water effectively reflects the composition of past dripwater. We then evaluated the process behind the observed isotopic variations using a partial equilibration model. The experimental results are best explained when we assumed that a thin CaCO_3 layer surrounding the inclusion reacted with the water. The amount of CaCO_3 that reacted with the water is equivalent to 2% of the water inclusions in molar terms. These results suggest that the magnitude of the isotopic exchange effect has a minor influence on palaeo-temperature estimates for the Quaternary climate reconstructions.

1 Introduction

Speleothems have provided invaluable terrestrial climate records over historical (e.g., (Zhang et al., 2008)) and glacial-interglacial (e.g., Wang (2001); Wang et al. (2017)) time scales. Among multiple climate proxies in speleothems (Fairchild et al., 2006), the stable oxygen isotope ratio of CaCO_3 ($\delta^{18}\text{O}_{\text{ca}}$) is the most widely used hydroclimate proxy. Changes in $\delta^{18}\text{O}_{\text{ca}}$

have been interpreted as proxies for monsoon strength (Wang, 2001), precipitation amount (Wang et al., 2017) or temperature (Dorale, 1998; Mori et al., 2018) depending on the hydroclimatic setting of each cave site.

This indeterminate nature of the $\delta^{18}\text{O}_{\text{ca}}$ interpretation is related to the fact that $\delta^{18}\text{O}_{\text{ca}}$ values are mainly controlled by two factors: the temperature in the cave and the annual mean $\delta^{18}\text{O}$ value of the rain water. To overcome this ambiguity, the isotopic compositions of water in fluid inclusions in stalagmites have been regarded as important proxies (Schwarcz et al., 1976; McDermott, 2004). Cave dripwaters are sealed in micro-scale cavities as fluid inclusions, whose $\delta^{18}\text{O}$ value is usually close to the $\delta^{18}\text{O}$ value of local rain. Generally, stalagmites contain inclusion water, which accounts for 0.05 to 0.5 wt. % of a speleothem (McDermott, 2005). Thus, the isotopic compositions of fluid inclusions of stalagmites ($\delta^{18}\text{O}_{\text{fi}}$) trapped under humid conditions should directly preserve the $\delta^{18}\text{O}$ value of dripwater in the past.

$\delta^{18}\text{O}_{\text{fi}}$ values are also useful for estimating past temperature variations. Although experimental studies suggest that the $\delta^{18}\text{O}_{\text{ca}}$ values of speleothems are affected by kinetic effects (e.g., Hansen et al. (2019); Dietzel et al. (2009)), a modelling study suggests a relatively stable value for the temperature dependence of $\delta^{18}\text{O}_{\text{ca}}$ values (Mühlinghaus et al., 2009). The combination of the two isotopic compositions, $\delta^{18}\text{O}_{\text{fi}}$ and $\delta^{18}\text{O}_{\text{ca}}$, provides a direct estimate for the oxygen isotopic fractionation between calcite and water, which is controlled mainly by the formation temperature. Thus, variations in past temperature (i.e., not absolute values but relative changes) can be estimated on the assumption that the kinetic effect is constant during the speleothem formation period.

Early studies analysed the hydrogen isotope ratio of fluid inclusions water ($\delta\text{D}_{\text{fi}}$), and the $\delta^{18}\text{O}_{\text{fi}}$ value was inferred from the modern δD vs $\delta^{18}\text{O}$ relation in meteoric water (Schwarcz et al., 1976; Harmon et al., 1979; Genty et al., 2002; Matthews et al., 2000; McGarry et al., 2004). These studies measured $\delta\text{D}_{\text{fi}}$ because of the technical difficulties associated with measuring the small amounts required to estimate $\delta^{18}\text{O}_{\text{fi}}$ values and a fundamental concern about the integrity of the $\delta^{18}\text{O}_{\text{fi}}$ data, namely, oxygen isotopic exchange between inclusion water and host calcite in speleothems.

After being trapped in the host calcite, inclusion water may continue to exchange oxygen isotopes with the surrounding host calcite as follows:

This isotopic re-equilibration effect potentially alters the $\delta^{18}\text{O}_{\text{fi}}$ values after the initial trapping of the inclusion water in the stalagmite. Such post-depositional isotopic exchange does not occur for hydrogen because of the small amount of hydrogen in the host calcite. Many studies on geothermal water have shown positive $\delta^{18}\text{O}$ shifts from the global meteoric water line (GMWL) (Clark and Fritz (1999) and references therein). These data suggest the isotopic exchange of oxygen between the geothermal water and the host aquifer rocks. This observation is one of the reasons why the earlier studies mentioned above explored the δD values of fluid inclusions rather than $\delta^{18}\text{O}_{\text{fi}}$ values (Harmon et al., 1979; Matthews et al., 2000; McGarry et al., 2004).

65 Recently, because of technological developments involving continuous-flow isotope ratio mass spectrometry (Vonhof
et al., 2006) and cavity ringdown spectrometry (CRDS) (Uemura et al., 2016;Arienzo et al., 2013;Affolter et al., 2014),
isotopic data from fluid inclusion have been accumulating. Interestingly, these studies suggest that post-depositional
exchange is not significant. In fact, the fluid inclusions analyses of modern stalagmites have shown that their $\delta^{18}\text{O}_f$ values
are consistent with the $\delta^{18}\text{O}$ values of modern dripwaters (Griffiths et al., 2010;Dennis et al., 2001;Arienzo et al.,
2013;Uemura et al., 2016;Labuhn et al., 2015), although a post-depositional alternation induced by recrystallisation has been
70 suggested (Demény et al., 2016). Moreover, several studies successfully quantitatively estimated past temperatures at the
time of calcite formation (van Breukelen et al., 2008;Meckler et al., 2015;Uemura et al., 2016). Therefore, these data imply
that the oxygen isotopic exchange between inclusion water and stalagmite calcite appears to be limited and/or very slow over
natural temperature ranges.

The indirect evidence for the insignificant post-depositional effect cannot provide explanations for the mechanisms
75 behind this phenomenon. Thus, it is essential to investigate the isotopic exchange reaction and evaluate how much the past
temperature reconstruction would be biased by this effect. However, to our knowledge, no study has investigated the
magnitude of isotopic exchange within natural stalagmites. In addition to this natural process, the isotopic exchange reaction
may occur during the drying process of stalagmite samples at high temperatures, which was commonly conducted before
fluid inclusion measurement in the laboratory.

80 Here, we evaluate the isotopic exchange reaction between inclusion water and host calcite based on a laboratory heating
experiment of natural stalagmite samples. We conducted a heating experiment because a higher temperature induces an
increase in the degree of isotopic disequilibrium between water and calcite and increases the rate of isotopic exchange. As a
result, an isotopic shift caused by the exchange reaction will be easier to detect. The stalagmite samples and experimental
settings are described in Section 2. Section 3 presents the experimental results and discusses them using an isotopic
85 exchange model for inclusion water and host calcite. Concluding remarks are given in Section 4.

2 Methods

2.1 Speleothem samples

A stalagmite (named HSN1) was collected in Hoshino Cave, Minami-Daito Island, Okinawa, Japan ($25^\circ 51' 34''\text{N}$, 131°
 $13' 29''\text{E}$). The stalagmite is 246 mm in length, and most parts are milky white with thin transparent layers (Fig. 1). To
90 compare the isotope ratios of fluid inclusions after different heating times, ten layers, A-J, were taken (2.4-3.9 mm in
thickness) from a quartered section of the stalagmite (Tables 1 and 2). Then, 3-6 wedge-shaped chipped sub-samples (51-193
mg) were taken from each layer (the shape is illustrated in Uemura et al., 2016). The sub-samples from the same depth
interval were assumed to have the same isotopic compositions.

2.2 Isotope measurements

95 The oxygen and hydrogen isotopic compositions of the water in the fluid inclusions were measured using a homemade
extraction device (Uemura et al., 2016). Briefly, the speleothem sample was crushed under vacuum, and then extracted water
vapour was transferred to a CRDS isotope ratio analyser (L2130-I, Picarro Inc.) at the University of the Ryukyus. Compared
with the system described in (Uemura et al., 2016), the system has been improved in three ways. (1) The valves were
automatically controlled using pneumatic valves. (2) The entire system was heated at 105°C because most parts were easily
100 damaged at 150°C. (3) The water vapour extracted from the stalagmite was immediately trapped cryogenically at the
temperature of liquid nitrogen, thereby preventing interaction between CaCO₃ and water vapour. The 1σ reproducibility for
the inclusion water analysis was ±0.3‰ for δ¹⁸O and ±1.6‰ for δD.

Stalagmite carbonate sub-samples were measured using an isotope ratio mass spectrometer (Thermo DELTA V
Advantage) equipped with a Thermo Gasbench II system at the University of the Ryukyus. Powdered sub-samples of 150-
105 200 μg were reacted with 100% phosphoric acid at 72°C in septa-capped vials before measuring the released CO₂. The 1σ
reproducibility for the analysis was ±0.04‰ for δ¹⁸O and ±0.03‰ for δ¹³C.

The isotopic composition is expressed in units of per mill (‰) using delta notation ($\delta = R_{\text{sample}}/R_{\text{ref}} - 1$), where R is the
isotopic ratio and R_{sample} and R_{ref} are the isotopic ratios of the sample and reference, respectively. For water samples from
fluid inclusions, δ¹⁸O and δD data are presented relative to Vienna standard mean ocean water (VSMOW) and are
110 normalized to the VSMOW-SLAP scale. For calcite samples, δ¹⁸O and δ¹³C data are expressed relative to the Vienna Pee
Dee Belemnite (VPDB) and/or VSMOW references. For clarity, the δ values of fluid inclusion water and stalagmite calcite
are expressed with the subscripts “fi” and “ca”, respectively. δ¹⁸O_{fi}, for example, indicates the δ¹⁸O value of the water in
fluid inclusions.

2.3 Heating experiment

115 To evaluate the effect of isotopic exchange between water and host calcite, a heating experiment was conducted. As a
pretreatment process, each stalagmite sample was placed in a small glass tube (o.d. 1/2 inch and 6 cm in length) with an
airtight screw cap sealed with two Viton O-rings. Then, the samples were dried in a vacuum line for 17 hours at room
temperature using a turbo molecular pump (with a pressure down to 10⁻⁵ Pa).

After this pre-drying process for all samples, the sample tube was subjected to different temperatures of 105°C or 25°C.
120 For the 105°C heating experiment, the sample tube was heated with a silicone cable heater at 105°C for a defined time period
(from 0 to 70 hours) under the same vacuum conditions (i.e., a pressure down to 10⁻⁵ Pa). For comparison, we also
performed a non-heating experiment at room temperature (25°C) for the same time periods (from 0 to 70 hours) under the
same vacuum conditions.

Then, the heated (or non-heated) sample was transferred in the closed sample tube to the fluid inclusion analysis
125 apparatus so that atmospheric exposure when introducing the sample lasted for less than 30 seconds. To evacuate the

analytical line, the samples were subjected to an additional 105°C condition for 20 minutes. Then, the sample was crushed, and the isotopic composition of the inclusion water was measured as described in Section 2.2.

3 Results and discussion

3.1 Isotope composition of inclusion water

130 The temporal variations in $\delta^{18}\text{O}_{\text{fi}}$ and $\delta\text{D}_{\text{fi}}$ values resulting from the 105°C heating and non-heating experiments are shown in Fig. 2. The isotopic compositions of inclusion water were shown as a deviation from the initial value ($\Delta\delta^{18}\text{O}_{\text{fi}}$ and $\Delta\delta\text{D}_{\text{fi}}$). For the 105°C heating experiment, the $\delta^{18}\text{O}_{\text{fi}}$ values gradually increased with the heating time and then reached a constant value after ca. 20 hours (Fig. 2a). The regression curve of the data represents an exponential function (Section 3.5). The $\delta^{18}\text{O}_{\text{fi}}$ values increased by ca. 0.7‰ with respect to the initial values during ca. 20 hours from the start of heating (Fig. 135 2a). In contrast, no significant trend was found for $\Delta\delta\text{D}_{\text{fi}}$ for the 105°C heating experiment (Fig. 3b). For the room-temperature drying experiment, neither $\Delta\delta^{18}\text{O}_{\text{fi}}$ nor $\Delta\delta\text{D}_{\text{fi}}$ values showed any systematic variation (Fig. 2c and 2d).

Overall, the results suggest that the observed increase in $\delta^{18}\text{O}_{\text{fi}}$ values in the 105°C heating experiment is caused by the oxygen isotopic exchange between inclusion water and the surrounding calcite. The data from the control experiment at room temperature suggest that the oxygen isotopic exchange reaction is too small to detect under 25°C conditions. The $\delta\text{D}_{\text{fi}}$ 140 data for the 25°C experiment confirms that there is no systematic isotopic variation caused by subsample cutting and length of drying time. In addition, the $\Delta\delta\text{D}_{\text{fi}}$ value for the 105°C experiment did not change because there is little hydrogen reservoir in calcite.

3.2 Evaporation during heating

Long-term heating may induce leakage from water inclusions through microscopic channels in the calcite caused by 145 decrepitation of the calcite. The measured water content (weight ratio of water in fluid inclusions to carbonate) of the experiments is shown in Fig. 3. Overall, the water content ranged from 0.05 to 0.3 wt. %, which is within the typical observed range of 0.05-0.5% (McDermott, 2005).

Although there are large variations in water content among different layers, there is no significant trend between heating time and water content (Fig. 3). This result suggests that the fluid inclusion water does not evaporate/leak even after long- 150 term heating. In addition, this finding suggests that our standard drying procedure (17 hours at room temperature, as described in Methods) is enough to remove the water adsorbed onto the calcite. Therefore, this result confirms that the increase in $\delta^{18}\text{O}_{\text{fi}}$ values (Fig. 3) in the heating experiments is not caused by evaporation due to thermal decrepitation.

3.3 Evidence of a post-depositional effect in the D-O plot

The distinct behaviour of $\delta\text{D}_{\text{fi}}$ and $\delta^{18}\text{O}_{\text{fi}}$ values is clearly depicted in the $\delta\text{D}-\delta^{18}\text{O}$ plot (Fig. 4). The GMWL and local 155 meteoric water line (LMWL) on Okinawa-jima Island in the summer and winter seasons are shown in Fig. 4. The LMWL is

calculated based on present-day rain water data from Okinawa-jima Island (Uemura et al., 2012), ca. 400 km west of Minami-daito Island. Although the initial δD_{fi} and $\delta^{18}O_{fi}$ values in the 25°C experiment are scattered between the summer and winter LWMLs, the $\delta^{18}O_{fi}$ values of the heating experiment are systematically shifted in the isotopically enriched direction. The average $\delta^{18}O_{fi}$ value of the heating experiments ($-5.4 \pm 0.4\%$) is higher than that of the 25°C experiment
160 ($-6.1 \pm 0.3\%$) by 0.7%. In contrast, the average value of δD does not differ between these experiments ($-34.5 \pm 1.9\%$ in the heating experiment, $-33.9 \pm 1.3\%$ in the room-temperature experiment).

Such positive $\delta^{18}O$ shift is opposite to the negative $\delta^{18}O$ shift of inclusion water in speleothems possibly induced by recrystallisation (Demény et al., 2016). Instead, the positive shift is similar to the $\delta^{18}O$ shift from GMWL found in observations of geothermal water (Clark and Fritz, 1999). Although the magnitude of the shift is much larger for geothermal
165 water, 5-15‰, the $\delta^{18}O_{fi}$ shift found in our experiment is likely caused by the exchange of ^{18}O between the inclusion water and the host calcite. The possible reasons for the small magnitude of the $\delta^{18}O$ shift, 0.7‰, in our experiment will be discussed later (Section 3.4 and 3.5).

In fluid inclusion studies, closeness to the LMWL in δD - $\delta^{18}O$ plots has been used as proof for the validity of analytical methods and the integrity of the sample. Our result calls for caution regarding the δD - $\delta^{18}O$ plot test. Most of the inclusion
170 data from the heating and room-temperature experiments are distributed between the summer and winter LWMLs. As discussed above, the artificial increase in the $\delta^{18}O$ value by heating is systematic. However, it is difficult to detect such a shift in the δD - $\delta^{18}O$ plot because the shift is small in the scattered data points. The data from the heating experiment (more than 10 hours) plot outside the summer LMWL, but a 0.7‰ deviation could be interpreted as resulting from different climate conditions. Because the oxygen isotopic exchange results in higher $\delta^{18}O$ values without a δD shift, the isotopic exchange
175 results in a lower deuterium excess value ($d = \delta D - 8 \delta^{18}O$), -6% shift in our experiment. Therefore, the low deuterium excess value of inclusion water can potentially be used as an indicator for the existence of oxygen isotopic exchange.

3.4 Partial isotopic exchange between water and calcite

To interpret the experimental result, we consider two hypotheses: (i) the oxygen isotopic exchange reaction occurred between inclusion water and the entirety of the host calcite (hereafter referred to as the “fully reacted hypothesis”) and (ii)
180 the $\delta^{18}O_{fi}$ values are equilibrated with a limited amount of $CaCO_3$ (hereafter referred to as the “partially reacted hypothesis”). These hypotheses are schematically explained in Fig. 5.

For the fully reacted hypothesis, the number of oxygen atoms in calcite can be considered infinite compared with that in the water inclusions because the water content of a stalagmite is very small: 0.05-0.5 wt. % (McDermott, 2005). Thus, the $\delta^{18}O_{fi}$ is simply controlled by the $\delta^{18}O$ value of calcite and the equilibrium fractionation factor between $CaCO_3$ and H_2O at
185 the ambient temperature (Fig. 5b). At 105°C, the fractionation factor between $CaCO_3$ and water is 1.0167. Because the $\delta^{18}O_{ca}$ value of HSN1 stalagmite is 25.5‰ vs VSMOW (i.e., -5.3% vs VPDB), the $\delta^{18}O_{fi}$ value in equilibrium with the calcite should be 8.6‰ vs VSMOW. Thus, $\delta^{18}O_{fi}$ value should be enriched by 14 to 15‰. This simple hypothesis, however, is not

realistic because the inclusion water likely reacts only with the inner surface of CaCO₃ surrounding the inclusions. In fact, the results in Fig. 2a show that the actual change in the δ¹⁸O_{fi} value is only 0.7‰.

190 The small δ¹⁸O_{fi} shift observed in the experiment can be interpreted as the result of (i) insufficient reaction time between water and calcite and/or (ii) reaction with a limited amount of CaCO₃. The first hypothesis can be rejected because the Δδ¹⁸O_{fi} enrichment plateaued within 20 hours (Fig. 2a). Therefore, the experimental results support the latter hypothesis. A model for this partially reacted hypothesis will be discussed in the following section.

3.5 Isotopic re-equilibration model

195 We describe a partial isotopic equilibration model that considers the changes in δ¹⁸O_{fi} values from the time when the inclusion water was entrapped in CaCO₃ (time 0) to a certain time required to reach a new isotopic equilibrium (time t₁; at a certain temperature T₁). An example of this re-equilibration scenario is that inclusion waters at room temperature (time = 0, temperature = T₀) are heated to 105°C (T₁) and reach a new isotope equilibrium at time t₁.

200 For the partially reacted hypothesis, we assumed that a limited amount of CaCO₃ in the reacted layer exchanged oxygen isotopes with the inclusion water (Fig. 5a). The isotope mass balance between the initial and partially equilibrated conditions at a heating time during a course of reaction at time t can be written as follows:

$$3 \cdot \gamma \delta_{ca_ra(0)}^{18} + \delta_{fi(0)}^{18} = 3 \cdot \gamma \delta_{ca_ra(t)}^{18} + \delta_{fi(t)}^{18} \quad (2)$$

205 where γ is a molar ratio of CaCO₃ involved in the reaction to the inclusion water (i.e., γ = CaCO₃ in reacted layer / H₂O in inclusion: M_{CaCO3}/M_{H2O}), δ¹⁸_{ca_ra(t)} indicates the δ¹⁸O value of the CaCO₃ in the reacted layer, and δ¹⁸_{fi(t)} indicates the δ¹⁸O value of the inclusion water at time t. If the CaCO₃ does not react with the water (i.e., γ = 0), for example, the δ¹⁸O_{fi} value does not change before and after the reaction.

At t₁, the δ¹⁸_{ca_ra(t)} and δ¹⁸_{fi(t)} reach an isotopic equilibrium state. This equilibrium state can be written as:

210

$$\delta_{ca_ra(t_1)}^{18} - \delta_{fi(t_1)}^{18} = \varepsilon_{T_1}^{18} \quad (3)$$

where ε¹⁸_{T₁} indicates the oxygen isotopic enrichment factor at the temperature T₁. Since the isotopic exchange reaction is considered to be faster when the isotopic difference, (δ¹⁸_{ca_ra(t)} - δ¹⁸_{fi(t)}), differs markedly from the isotopic enrichment factor at the new equilibrium state (ε¹⁸_{T₁}), the reaction can be written as:

$$-\frac{d(\delta_{ca_ra(t)}^{18} - \delta_{fi(t)}^{18} - \varepsilon_{T_1}^{18})}{dt} = k_{18}(\delta_{ca_ra(t)}^{18} - \delta_{fi(t)}^{18} - \varepsilon_{T_1}^{18}) \quad (4)$$

where k_{18} indicates a reaction constant. The integration of Eq. (4) yields:

220

$$(\delta_{ca_ra(t)}^{18} - \delta_{fi(t)}^{18} - \varepsilon_T^{18}) = (\varepsilon_{T_0}^{18} - \varepsilon_{T_1}^{18}) \exp(-k_{18}t) \quad (5)$$

where $\varepsilon_{T_0}^{18}$ ($= \delta_{ca_eq(0)}^{18} - \delta_{fi(0)}^{18}$) represents the oxygen isotopic enrichment factor at the initial temperature of T_0 .

To fit our experimental data, in which we measured the difference between heated and initial (i.e., non-heated) conditions, we took the difference between Eq. (5) and the initial condition ($t = 0$) of Eq. (5) ($\delta_{ca_eq(0)}^{18} - \delta_{fi(0)}^{18} - \varepsilon_{T_1}^{18} = \varepsilon_{T_0}^{18} - \varepsilon_{T_1}^{18}$). Thus, with Eq. (2), we obtain

225

$$\Delta\delta_{fi(t)}^{18} = \left(\frac{3\gamma}{1+3\gamma}\right)(\varepsilon_{T_0}^{18} - \varepsilon_{T_1}^{18}) (1 - \exp(-k_{18}t)) \quad (6)$$

where $\Delta\delta_{fi(t)}^{18}$ ($= \delta_{fi(t)}^{18} - \delta_{fi(0)}^{18}$) represents the $\delta^{18}\text{O}_{fi}$ difference between the reacted and initial conditions. When the new equilibrium state is reached ($t = t_1$), Eq. (6) yields:

230

$$\Delta\delta_{fi(t_1)}^{18} = \left(\frac{3\gamma}{1+3\gamma}\right)(\varepsilon_{T_0}^{18} - \varepsilon_{T_1}^{18}) \quad (7).$$

This equation provides an estimate of γ based on the experimental results.

235

A regression curve based on Eq. (5), is shown in Fig. 2a. Based on Eq. (7), the value of γ is estimated to be 0.02. This suggests that the amount of CaCO_3 reacted with water is equivalent to 2% of the water inclusions in molar terms. The thickness of the reacted layer of CaCO_3 can be roughly estimated on the assumption that the fluid inclusions filled with water are cubic with 50 μm edges. With a calcite density of 2.71 g/cm^3 , the thickness of the reacted layer of CaCO_3 is estimated to be 0.6 μm .

240

This result is explained schematically in Fig. 5a and 5c. The $\delta^{18}\text{O}_{fi}$ value increased by only 0.7‰. Since the equilibrium fractionation factor between CaCO_3 and water at 105°C is 1.0167, the $\delta^{18}\text{O}_{ca}$ of the reacted layer should be 11.3‰ vs VSMOW. Thus, in this case, the $\delta^{18}\text{O}_{ca}$ value of the reacted layer changed significantly.

3.6 Impact for palaeo-climate reconstruction

In this section, we estimate the impact of the isotopic exchange effect on Quaternary palaeo-climate reconstructions. First, at 105°C, detectable isotopic exchange occurred within 20 hours. This finding suggests that researchers should be aware of this effect during experimental procedures, such as the heat drying process, before fluid inclusion measurements. Second, we consider a case in which the dripwater enclosed in the fluid inclusions during a glacial period with a temperature of 15°C re-equilibrates at the modern average temperature of 25°C. The isotopic enrichment factors (ε_T^{18}) for 15°C and 25°C

245

250 are 30.6‰ and 28.4‰, respectively. Thus, based on Eq. (7) with a γ value of 0.02, the fluid inclusion oxygen isotope ratio $\delta^{18}\text{O}_{\text{fi}}$ would increase by only 0.1‰. With the temperature dependence of the $\delta^{18}\text{O}$ fractionation factor between water and calcite (0.2‰/°C), this isotopic exchange results in a 0.5°C bias in the palaeo-temperature estimate. We should note that we do not know the reaction rate of the isotopic exchange under normal ambient temperatures. Calcite and fluid inclusion water might not reach a new equilibrium state even after thousands of years. Thus, this estimate is an upper limit of the bias.

255 Because the bias, 0.1‰, is within the typical analytical error for inclusion analyses, the post-depositional effect has little influence on the palaeo-temperature estimates for glacial-interglacial cycles.

4 Conclusions

Our experiment shows that the $\delta^{18}\text{O}$ values of fluid inclusion water in speleothems changes because of isotopic exchange reactions with the host calcite. Unlike the $\delta^{18}\text{O}$ value of inclusion water, the δD value showed no trend even after

260 prolonged heating and thus effectively reflects the original isotopic composition of past dripwater. This study is the first to present experimental data showing that such a post-depositional effect occurs in natural speleothem samples. However, the changes in the $\delta^{18}\text{O}$ values of fluid inclusion were very small, 0.7‰, in the 105°C heating experiment. Based on this result, the inclusion water reacts only with a thin layer of surrounding CaCO_3 . The amount of CaCO_3 that reacted with the water is equivalent to 2% of the water inclusions in molar terms. Thus, the oxygen isotopic exchange results in a minor impact on the

265 estimation of past temperature changes: a maximum bias of 0.5°C for a 10°C climate shift. This study provides a quantitative explanation of the mechanism by which the effect of isotopic exchange appears to be insignificant in previous speleothem studies. The results also suggest that the sample treatment in the laboratory (i.e., heated drying process) should be conducted with caution because isotopic exchange may affect the $\delta^{18}\text{O}$ value of fluid inclusions.

270 Data availability

The data generated and used in this study are available in Tables 1 and 2 in this article.

Author contributions.

RU designed the experiment and study. YK and KO conducted the experiments. All authors contributed to the discussion. RU analysed the results, generated figures and wrote the paper.

Figures

Figure 1: Photographs of HSN1 stalagmite.

375

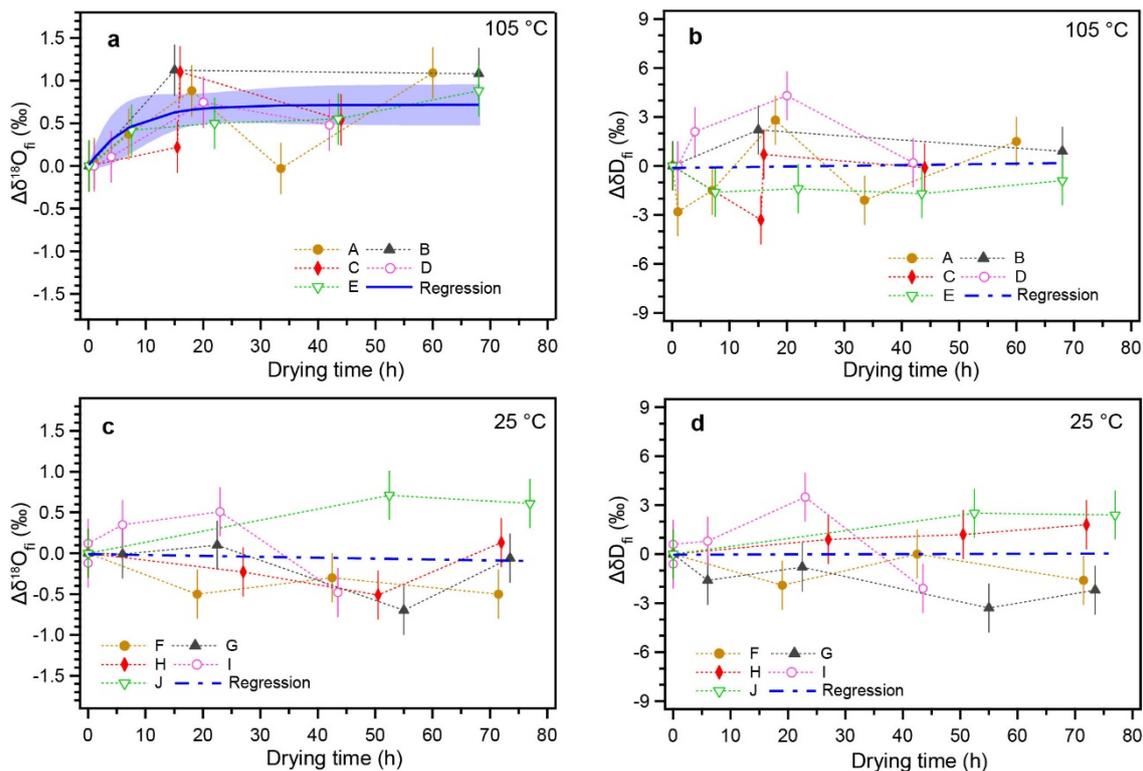

Half section of the HSN1 stalagmite from Hoshino Cave. The horizontal bar represents 5 cm.

380

Figure 2: Changes in isotopic compositions of inclusion water with increasing drying time.

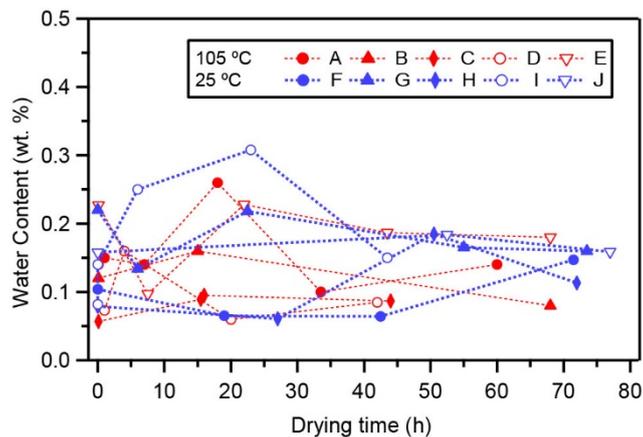

385

a) Changes in the $\delta^{18}\text{O}$ value of inclusion water from the initial value ($\Delta\delta_{fi}^{18}(t)$) with time under 105°C heating. Time on the x-axis indicates drying time in addition to the standard 17-hour drying process at room temperature. **b)** The same as **a)** but for δD_i . **c)** Changes in the $\Delta\delta_{fi}^{18}(t)$ value over time at room temperature (25°C). **d)** The same as **c)** but for δD_i . The error bar of the data point represents the analytical reproducibility (1σ). The regression curve (blue) in panel **a)** was calculated with IGOR (Wave Metrics Inc.) software to fit a function ($\Delta\delta_{fi}^{18} = A(1 - \exp(-k t))$) ($A = 0.71$; $k = 0.14$). The blue shade indicates the 95% confidence interval. Blue dashed lines in panels **b-d)** indicate linear regression lines (the correlations are insignificant).

395

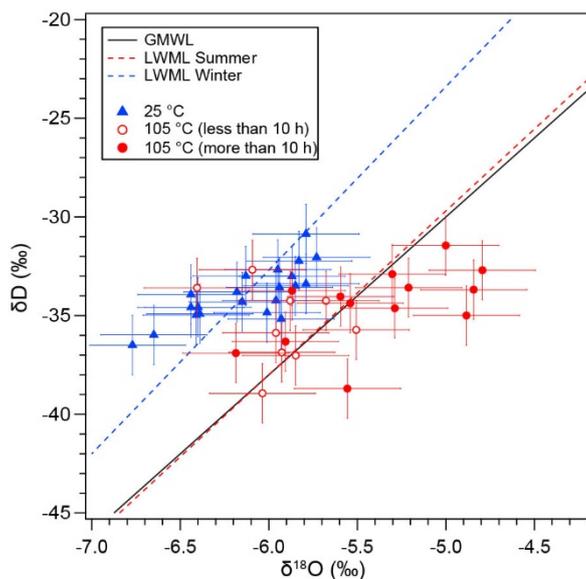

Figure 3: Changes in water content with increasing drying time.

Changes in water content (in wt.%) of each subsample with time (in hour). Symbols indicate the 105°C experiment (red, layer A-E) and 25°C drying experiment (blue, layer F-J).

Figure 4: D-O plot of inclusion water.

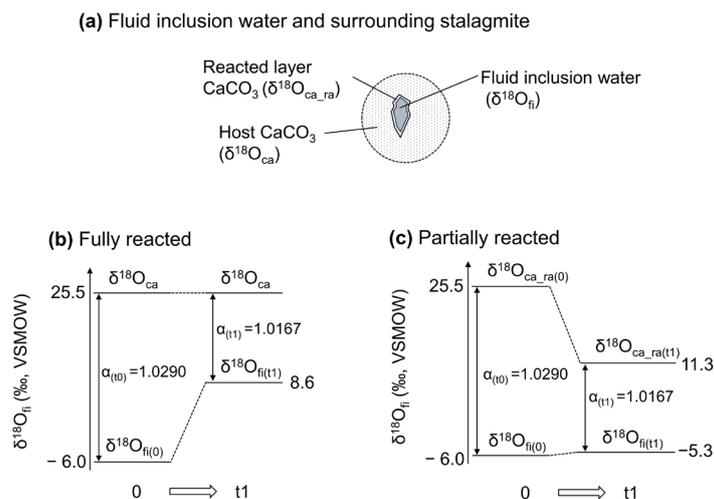

405 The blue triangles indicate the isotopic compositions of the fluid inclusion in the 25°C drying experiment. The red circles indicate the isotopic compositions of the fluid inclusion in the 105°C drying experiment for < 10 hours (open red circles) and >10 hours (solid red circles). The black line indicates GMWL. Local meteoric water lines based on present-day raindata from Okinawa-jima Island for the summer season (red dotted line) and the winter season (blue dotted line) are also shown.

410

Figure 5: Schematic illustration of isotopic re-equilibration between inclusion water and stalagmite.

(a) Schematic illustration of a water-filled fluid inclusion and surrounding CaCO_3 . (b) Changes in the isotopic composition for the fully reacted hypothesis, in which the $\delta^{18}\text{O}_{\text{fi}}$ value changes in response to equilibration with an infinite amount of host CaCO_3 . In this case, the sample at room temperature (25°C at time of 0) is heated to 105°C and reaches a new isotopic equilibrium at time t_1 . (c) The same as (b) but for the partially reacted hypothesis, in which the $\delta^{18}\text{O}_{\text{fi}}$ value changes in response to equilibration with a limited amount of CaCO_3 . Note that the calcite-water fractionation factor is the same for both hypotheses.
